COLLEGE OF MEDICINE LIBRARY U.S.

OFFICIAL JOURNAL OF THE
AMERICAN PSYCHIATRIC ASSOCIATION

Basic tool of primitive psychiatry

Herbalist's staff (pa osanyin), with birds (wrought iron), Yoruba tribe, Nigeria, 21 inches.

This staff is topped by a circle to which 16 small birds (a magical number) are attached. The single bird in the middle symbolizes the witch who causes sickness or death. The staff is placed next to the shrine of Osanyin (the god of the herbalist), along with eggs and kola, to neutralize the witch's evil spirit. Sometimes the staff is also placed next to the bed of a sick person to chase away the disease-causing spirit.

From the collection of the Segy Gallery, New York City. Reproduced with permission.

Basic tool of modern psychiatry

Thorazine®

Tablets: 25 mg of the HCl

brand of chlorpromazine

- 'Thorazine' effectively controls psychotic symptoms
- Especially useful in agitated, violent or anxious schizophrenic patients
- Unsurpassed clinical experience
- 18 convenient dosage forms and strengths

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings:

Caution is recommended when 'Thorazine' is administered for the treatment of vomiting in children.

Antiemetics are not recommended to treat uncomplicated short-term vomiting in children or vomiting of unknown etiology.

The possibility of extrapyramidal reactions from 'Thorazine' may confuse the diagnosis of Reye's syndrome or other encephalopathy. Although unconfirmed, some suspicion exists that centrally-acting antiemetics may contribute to or adversely affect the course of Reye's syndrome, and should be avoided in suspected cases.

©1967, 1968, 1969 SmithKline Corporation

Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudo-parkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis; contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.

NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, in 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; Single Unit Packages of 100 (intended for institutional use only). Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only). Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg. Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

APA PLACEMENT SERVICE
For Employers and Applicants

Those wishing to announce either position openings or availability for employment may register in advance by requesting a listing form by calling Ms. M. J. Merrick (202) 232-7878, ext. 326, or writing to her attention at APA Central Office, 1700 18th Street, N.W., Washington, D.C. 20009. Listing forms should be returned no later than September 26th. On-site listings will also be accepted. However, forms received at the APA prior to the September 26th deadline will have exposure from the very beginning of the Institute. There will be a Placement booth and an interviewing area located in the Institute Registration area (Georgian Room) at the St. Francis Hotel. Listings will be accepted for any mental health related position vacancy/availability.

APPLICANTS—$3 for listing availability
EMPLOYERS—$5 for listing job description

Complete sets of either all applicants or all positions will be available at the close of the Institute at $10 per set.

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit 3 copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later. Annual meeting papers should not be submitted to the *Journal* until *after* the annual meeting.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

All communications about a manuscript should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; with other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, the copyright of all parts of the paper, including any illustrations, passes from the author to the *Journal*. Written permission to reprint material published in the *Journal* must first be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for this permission.

Informed consent. Manuscripts that report the results of experimental investigation on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure had been fully explained.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

SPECIFICATIONS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond paper. **All parts of the manuscript** (including case reports, footnotes, references, etc.) **should be double spaced,** with margins of 2½-3¾ cm (1-1½ inches) at the top, bottom, and both sides. Subheads should be inserted at reasonable intervals. All abbreviations should be explained. All measurements must be in metric units.

Length. All pages of the manuscript must be numbered, including references, tables, and figures. The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles: 3,800 words or the equivalent including references, tables, and figures (about 15 manuscript pages). Brief Communications: 2,500 words or the equivalent (about 10 manuscript pages); see stipulations above. Clinical and Research Reports: 1,000 words. 10 references, 1 table. Letters to the Editor: 500 words. Please write the total number of words and the number of tables and figures on the title page of the submitted material.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the coauthor [redacted] been designated to assume responsibility for the paper a[redacted] print requests. Authors named in the by-line should be lim[redacted] to principal researchers and writers; other collaborators may be acknowledged in a footnote.

Precis. A brief precis (60–100 words for regular articles, 40–60 words for Brief Communications) is included at the beginning of each article. The author may prepare the precis or ask that the *Journal* staff prepare it.

References. References should be typed **double spaced** on a separate sheet of paper. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Tables and figures should be self-explanatory and should supplement, not duplicate, text. See recent issues of the *Journal* for general style.

Each table should be typed double spaced on a separate sheet attached at the end of the manuscript. Columns of like material should read down, not across.

One complete set of figures, in the form of glossy prints, should be submitted. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Graphs should be finished drawings not requiring further artwork. Authors are urged to engage professional assistance in the preparation of figures and may be charged for any further artwork that must be done in the editorial office.

AUTHORS CORRECTIONS

After the paper has been scheduled for publication, the edited manuscript will be sent to the first-named author for corrections and answers to queries. Prompt return is necessary. If an author expects to be away from his office for a long period of time after being notified of the acceptance of his paper, he should inform the *Journal* office or arrange with a coauthor to assume responsibility for the paper. Galley proofs will not be sent to authors.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Requests from others to order reprints should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

MELANIE KLEIN

With the publication of these two editions, Delta Books now has the complete works of Melanie Klein available in paperback.

LOVE, GUILT AND REPARATION & Other Works 1921-1945
This seminal work of the renowned pioneer in child psychoanalysis reveals Melanie Klein's intense preoccupation with the impact of infant anxieties upon child development and the psychogenesis of manic-depressive states. A major contribution to the understanding of infant development.
55114-5 $4.95

ENVY AND GRATITUDE & Other Works 1946-1963
This chronological collection of Melanie Klein's most mature work further explains her theories on the recognition and treatment of neuroses in early childhood. The title essay introduces Klein's controversial theory of primary envy, describing the conflict between infantile envy and gratitude and tracing its influence in later behavior.

  By Toksoz B. Karasu

CASSETTE LECTURES*
OF THE 130th ANNUAL MEETING
AMERICAN PSYCHIATRIC ASSOCIATION

PROGRAM I: 3 HOURS 3 CASSETTES $25.00

PSYCHOTHERAPY

OBESITY AND PSYCHOANALYSIS

PATIENT-THERAPIST MATCHING: A RESEARCH EVALUATION

BORDERLINE ADULT: THERAPEUTIC ALLIANCE AND TRANSFERENCE

BRIEF PSYCHOTHERAPY OF NARCISSISTIC DISTURBANCES

BRIEF THERAPY: THEORY AND PRACTICE

SELECTION OF TEMPORAL PARAMETERS IN PSYCHOTHERAPY

PROGRAM II: 3 HOURS 3 CASSETTES $25.00

CRITERIA FOR DIAGNOSIS 1

DSM-III: TIMELY OR PREMATURE?

RESEARCH DIAGNOSTIC CRITERIA: RATIONALE AND RELIABILITY

BLINDNESS AND RELIABILITY IN PSYCHIATRIC DIAGNOSIS

DO PSYCHIATRIC PATIENTS FIT THEIR DIAGNOSES?

DIAGNOSIS OF NON-PATIENTS IN THE GENERAL COMMUNITY

PROGRAM III: 3 HOURS 3 CASSETTES $25.00

PERSONALITY AND DEPRESSION: NEW APPROACHES

CYCLOTHYMIA AS SUBCLINICAL EXPRESSION OF DEPRESSION

DEPRESSION AND THE EVOLUTION OF PERSONALITY DISORDERS

MALADAPTIVE COGNITIVE TRAITS IN DEPRESSION

INTERPERSONAL DEPENDENCY: AN EMPIRICAL APPROACH

PROGRAM IV: 3 HOURS 3 CASSETTES $25.00

TREATMENT OF DEPRESSION AND ANXIETY

PREDICTORS OF AMPHETAMINE RESPONSE IN DEPRESSION

SHOULD MAO INHIBITORS BE ABANDONED?

DIAZEPAM INDUCED HOSTILITY IN DEPRESSION

BENZODIAZEPINES (TRIAZOLAM & FLURAZEPAM) AND COGNITIVE IMPAIRMENT

ANTIDEPRESSANT TREATMENT OF SEVERE PHOBIC ANXIETY

DOES THE LOCUS COERULEUS MEDIATE ANXIETY AND FEAR?

PROGRAM V: 3 HOURS 3 CASSETTES $25.00

NIMH-CRB CLINICAL COLLABORATIVE DEPRESSION STUDY

PATIENTS WITH AN AFFECTIVE SYNDROME: USE OF THE SCHEDULE FOR AFFECTIVE DISORDERS AND SCHIZOPHRENIA

USING THE RESEARCH DIAGNOSTIC CRITERIA TO STUDY AFFECTIVE DISORDERS

NEUROTIC DEPRESSION: A SYSTEMATIC ANALYSIS OF ITS MULTIPLE MEANINGS

FAMILIAL FACTORS IN AFFECTIVE DISORDERS

PERSONALITY ATTRIBUTES AND AFFECTIVE DISORDERS

CROSS-CENTER COMPARABILITY OF CLINICAL JUDGMENTS

PROGRAM VI: 3 HOURS 3 CASSETTES $25.00

PHENOMENOLOGY OF DEPRESSION

LIFE EVENTS AND THE ONSET OF BIPOLAR AFFECTIVE ILLNESS

THINKING AND LANGUAGE IN DEPRESSION

FAMILY DYNAMICS AND MANIC-DEPRESSIVE ILLNESS

PHENOMENOLOGY OF DEPRESSION IN ADOLESCENCE

SEROTONIN AND NOREPINEPHRINE SUBGROUPS IN DEPRESSION

PROGRAM VII: 3 HOURS 3 CASSETTES $25.00

PHENOMENOLOGY OF SCHIZOPHRENIA

ARE FIRST-RANK SYMPTOMS RELEVANT TO SCHIZOPHRENIA?

SCHIZOPHRENIA OF GOOD PROGNOSIS: A DISTINCT SYNDROME?

IS MODERN-DAY SCHIZOPHRENIC OUTCOME STILL NEGATIVE?

SCHIZOPHRENIC ASSOCIATIONS AND INTERMINGLING

JUDGING EMOTIONS IN NORMALS AND SCHIZOPHRENICS

PROGRAM VIII: 3 HOURS 3 CASSETTES $25.00

PSYCHOPHARMACOLOGY OF SCHIZOPHRENIA

LITHIUM IN PSYCHOTIC AND REMITTED SCHIZOPHRENICS

ANTIPARKINSONIANS AND PLASMA LEVEL OF NEUROLEPTICS

FACTORS RELATED TO TARDIVE DYSKINESIA

COVERT DYSKINESIA

AMANTADINE IN NEUROLEPTIC EXTRAPYRAMIDAL REACTIONS

EFFECT OF APOMORPHINE ON SCHIZOPHRENIC SYMPTOMS

PROGRAM IX: 3 HOURS 3 CASSETTES $25.00

SUICIDAL BEHAVIOR

HUMAN FACTORS IN CRASHES: CAUSES OR CORRELATES

DISGUISED SUICIDAL BEHAVIOR

DEPRESSIVES AT LOW AND HIGH RISK FOR SUICIDE

END OF THE OREGON TRAIL: SUICIDES -- 1894 THRU 1974

CASSETTES PACKAGED IN LIBRARY BINDER.

AV/MD, 850 THIRD AVENUE, NEW YORK, N.Y. 10022

Hallucinations and delusions rapidly controlled

Trapped by unrealistic perceptions...

...and terrified by his hallucinations and delusions on admission. Because Navane (thiothixene) is particularly effective in controlling these symptoms and their resulting suspiciousness and anxiety, it can provide the essential first step toward restoring stabilization and facilitating the development of purposeful activity. Extensive clinical data and widespread experience confirm the effectiveness of Navane in rapidly controlling such typical psychotic behavior on admission.

Long-term therapy is facilitated...

...because Navane offers an unsurpassed safety record among effective neuroleptic agents, permitting continuing control of symptoms of psychoses such as hallucinations and delusions. Like other antipsychotic agents, extrapyramidal symptoms may occur, but are readily controlled through dosage adjustments or antiparkinsonian agents. Cardiovascular effects such as hypotension, and hepatic or hematopoietic effects rarely occur and are generally mild and transient, with no jaundice or agranulocytosis reported to date.

An effective first step towards discharge...

Navane®
(thiothixene) (thiothixene HCl)

Capsules 1 mg., 2 mg., 5 mg., 10 mg., 20 mg. Concentrate 5 mg./ml.—Intramuscular 2 mg./ml.

For prescribing information, including adverse reactions and contraindications, please see following page of this advertisement.

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Actions. Navane is a psychotropic agent of the thioxanthene series. Navane possesses certain chemical and pharmacological similarities to the piperazine phenothiazines and differences from the aliphatic group of phenothiazines. Navane's mode of action has not been clearly established.

Indications. Navane is effective in the management of manifestations of psychotic disorders.

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy* – Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children—The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration – As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane. Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudoparkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leucocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution—For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate—In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

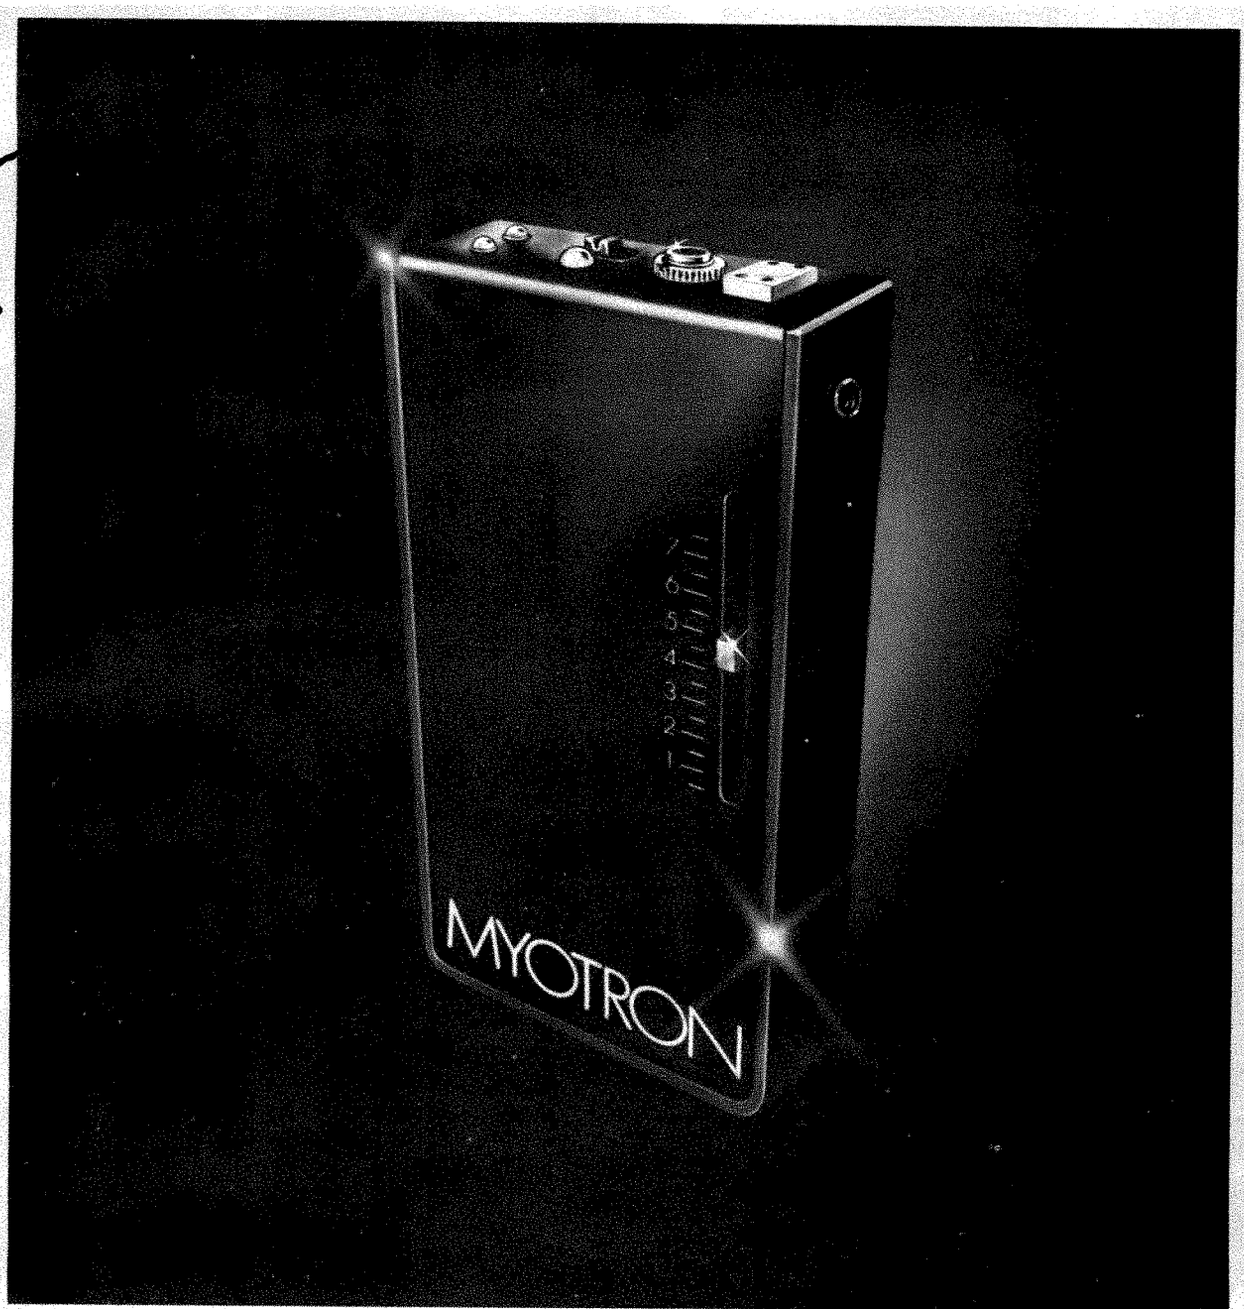
Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor elevating action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.



How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg. of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

ACTUAL SIZE

THE MYOTRON™ SYSTEM

The first complete pocketsize system to monitor muscle activity.

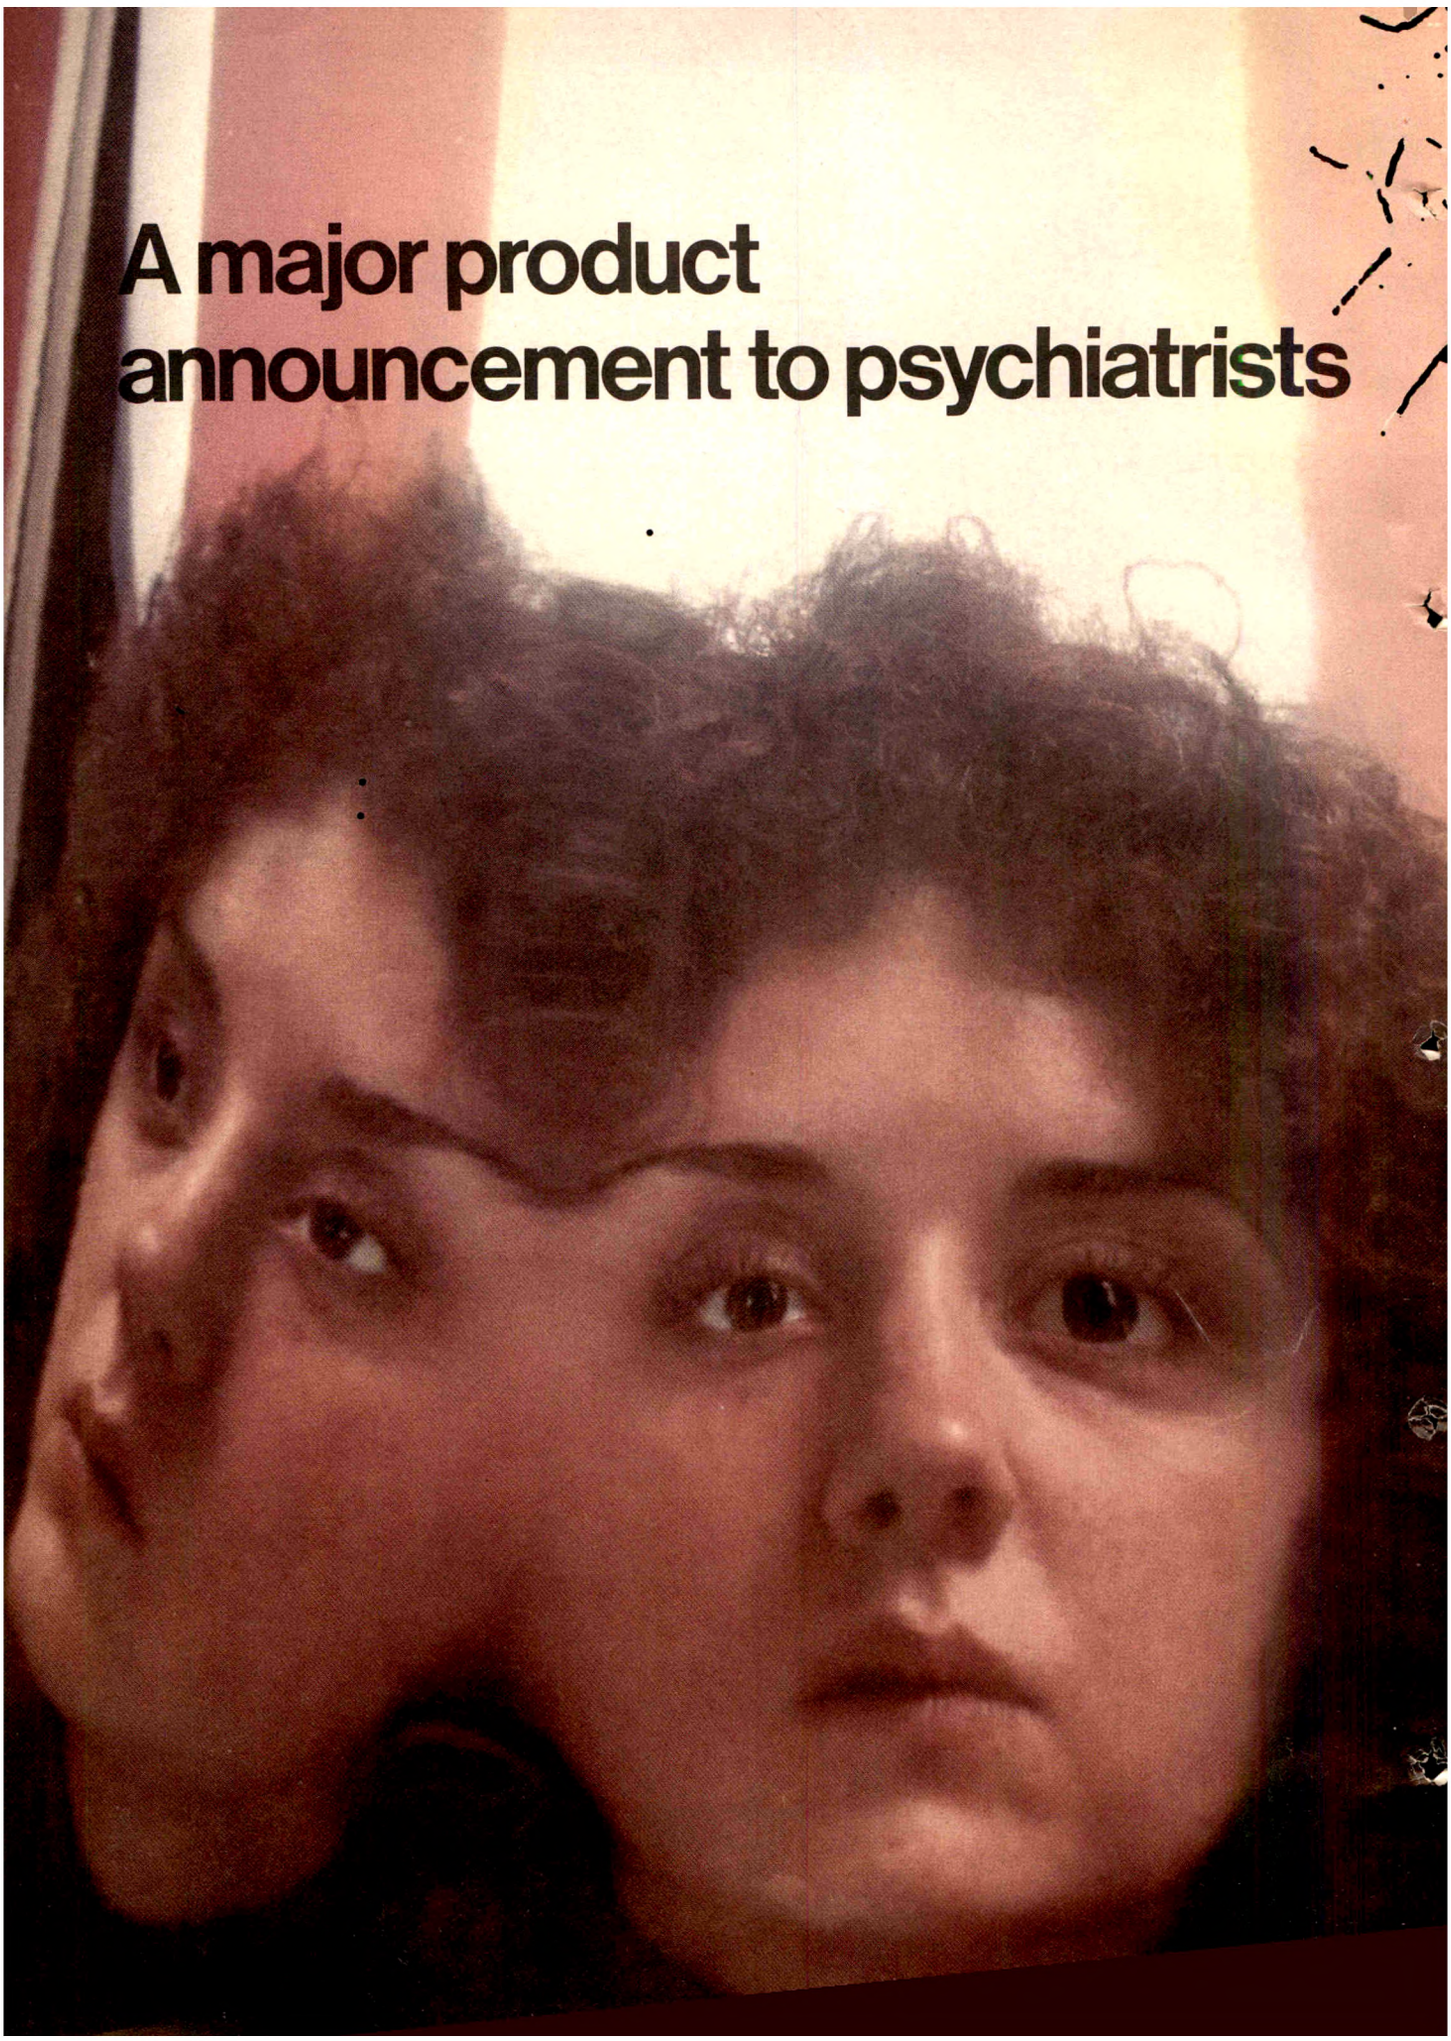
Immediate visual feedback: three light-emitting diodes.

Immediate audio feedback: includes earphone attachment.

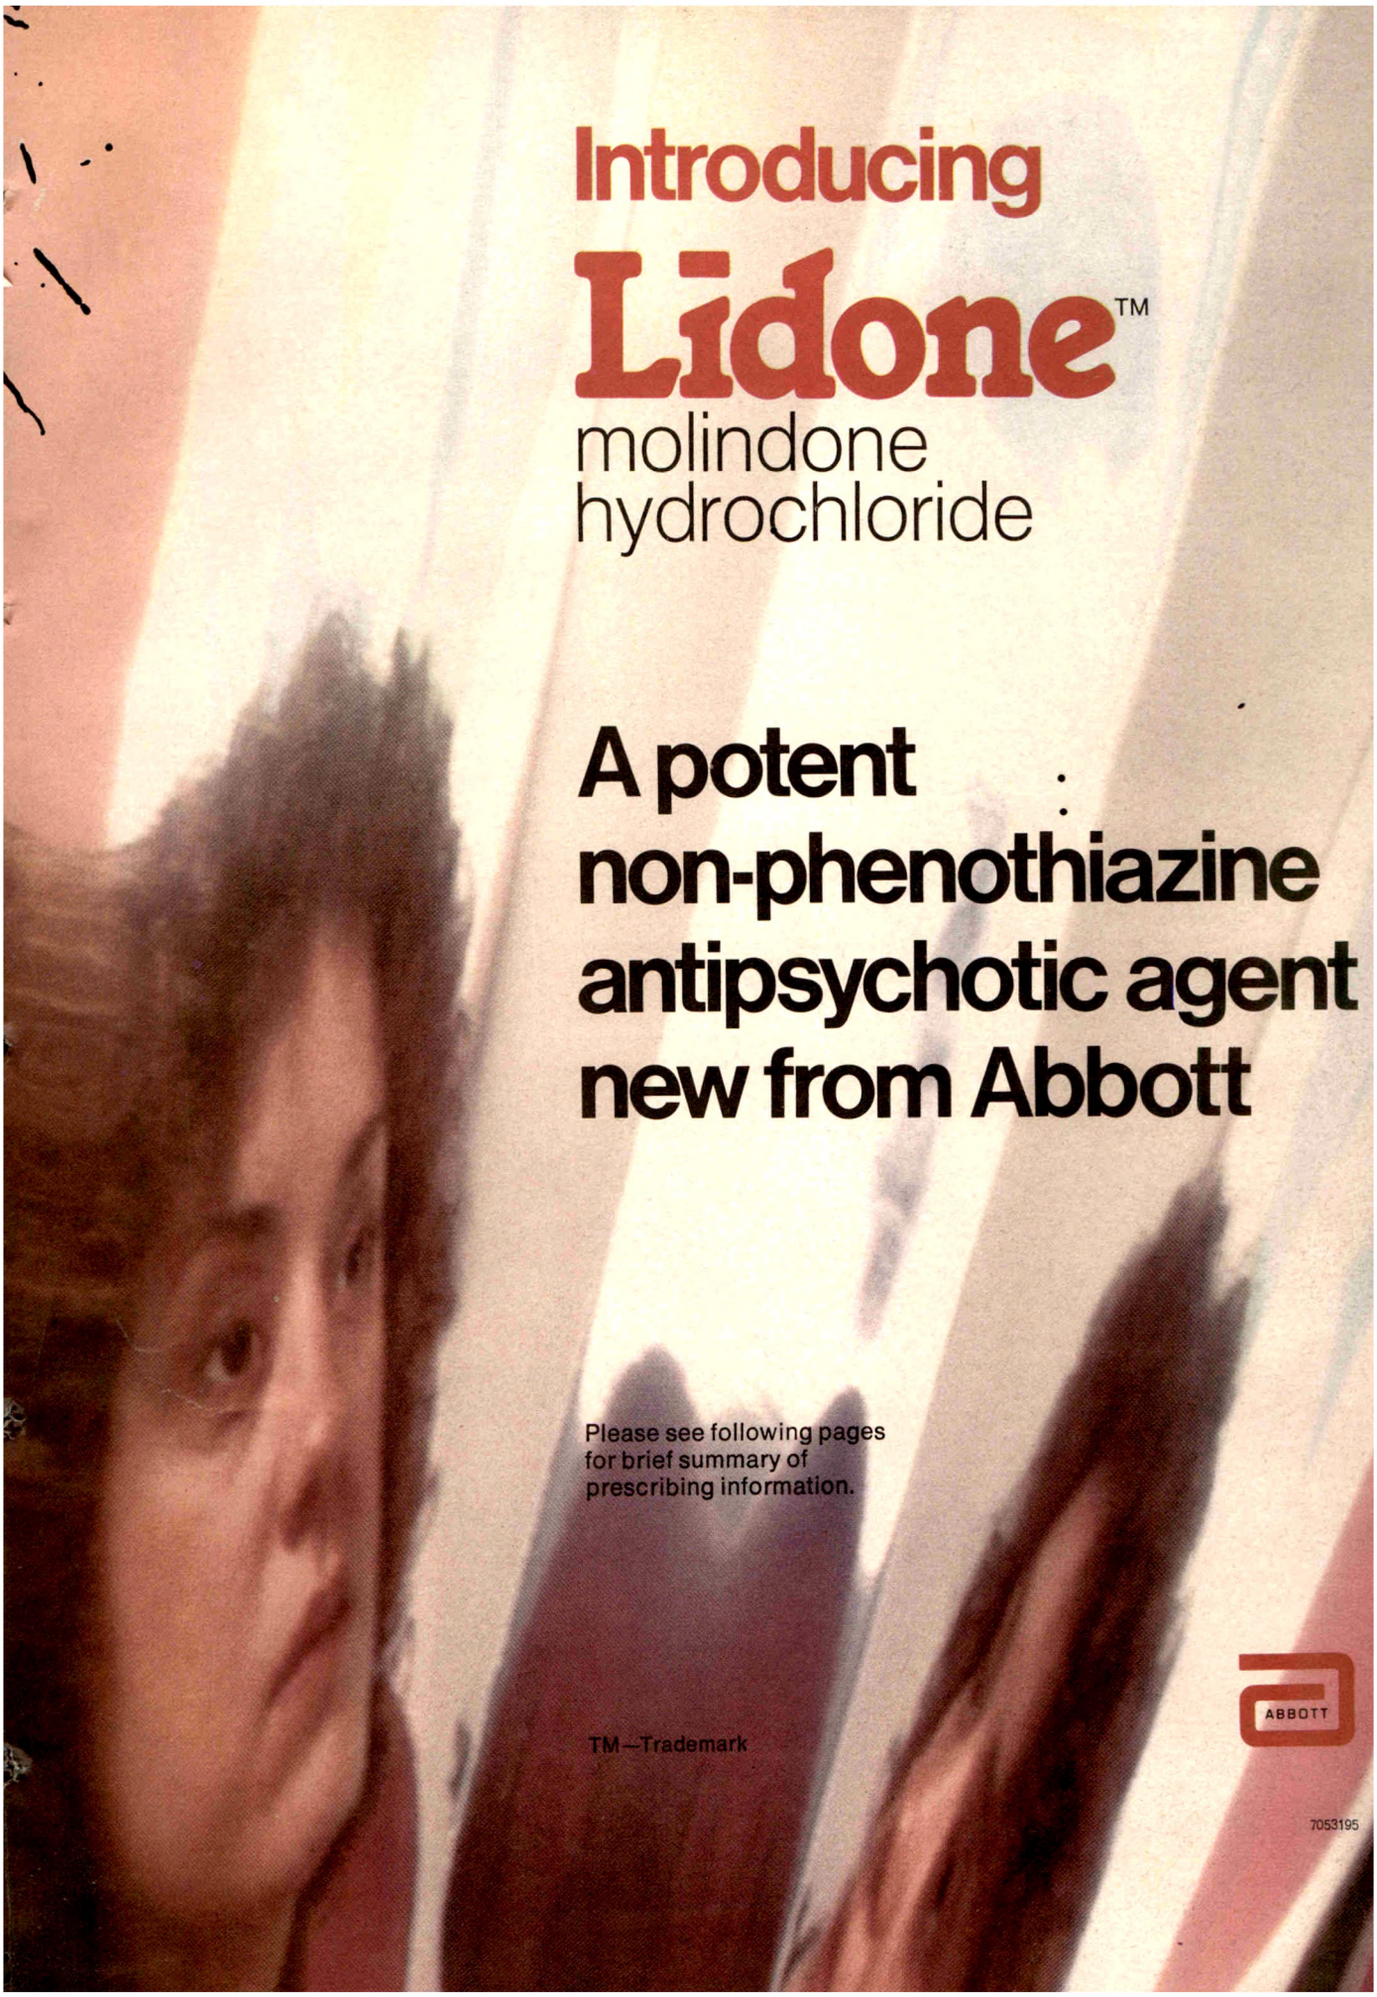
Lightweight, portable, compact: can be worn in shirt pocket.

Simple and convenient: ideal for both clinical and home use.

Calibrated response: measures and monitors muscle activity.



Remarkably quiet: heightened sensitivity to muscle relaxation.



High quality, low cost: state-of-the-art electronic circuitry.

molindone
hydrochloride

Why Lidone™ belongs among your first-line antipsychotic agents

Because of its effectiveness

Demonstrated control of target symptoms. Lidone is a non-phenothiazine antipsychotic agent, indicated for management of the manifestations of schizophrenia. As such it offers a clinically proven oral treatment effective over a broad range of target symptoms. Improvement has been reported in:

- Conceptual disorganization[1,2,6,9]
- Unusual thought content[3,4,11,12]
- Hallucinations[3,6,9,11]
- Hostility[1,10,11]
- Bizarre motor behavior[3,11,12]
- Retardation[2,8,12]

Improvement in social outlook. Lidone has enabled patients to display progress in social behavior, and improved social competence and interest.[2,7,9,12,13] Interpersonal relationships have accordingly benefited.

Because of its degree of safety

Seldom causes problem sedation. Lidone is classed among the less-sedating group of major tranquilizers. Initial drowsiness usually subsides with continued use.

Extrapyramidal effects usually controlled. These usually respond to appropriate management without cessation of drug therapy.

Significant hypotension rare; hematologic effects limited. Less than 1% incidence of significant hypotension has been reported in clinical studies, and only rare reports of leucopenia and leucocytosis.

No serious ocular effects, impotence, or excessive weight gain. Unlike some antipsychotic agents, Lidone has not been associated with these conditions.

Persistent tardive dyskinesia not reported. Only a few cases of late-occurring dyskinesia have been noted (reversible upon discontinuation of therapy), and there have been no reports of persistent tardive dyskinesia.

Other side effects comparable to other agents. See Brief Summary for a complete statement of adverse reactions.

Lidone™

molindone hydrochloride

Because of its benefits

Patients accessible to psychotherapy. Patients are seldom over-sedated with Lidone. They tend to remain alert and therefore responsive to psychotherapy and rehabilitation.

Social relationships not disrupted. Improved social behavior has been noted, and side effects which are potentially disruptive to social or family relationships (e.g., weight gain, sexual dysfunction) have not been a problem.

Permits continuity of drug therapy. Few of the side effects require discontinuation of drug therapy.

Most economical non-phenothiazine. The relatively low milligram cost and high milligram potency of molindone make it least expensive of the potent new non-phenothiazine antipsychotics, and also less costly than many leading phenothiazines.[14]

Unique alternative for refractory patients. Molindone is unrelated to other antipsychotic drug families. Hence Lidone may benefit patients who are unresponsive to, or who cannot tolerate, other agents.

Please see following page for brief summary of prescribing information.

Because of its ease of administration

Simple Oral Regimen according to severity of presenting symptoms:

Dose strength	Schizophrenic manifestations	Dosage regimen
5 mg	mild	5 mg three or four times daily. (An increase to 15 mg three or four times daily may be required).
10 mg	moderate	10 mg three or four times daily. (An increase to 25 mg three or four times daily may be required.)
25 mg	severe	Daily dosage as high as 225 mg may be required.

Dosage Comparison at approximately equipotent dose levels:

Agent	Comparable doses[14]
Chlorpromazine	100 mg
Thioridazine	100 mg
Lidone	10 mg
Trifluoperazine	5 mg
Thiothixene	3 mg*
Haloperidol	2 mg
Fluphenazine	2 mg*

*Product not supplied in this exact strength.

Supplied in bottles of 100 capsules

Dose strength	Drug code	Color
5 mg	NDC 0074-5542-13	blue and cream
10 mg	NDC 0074-5543-13	red and cream
25 mg	NDC 0074-5544-13	brown and cream

7053195

Brief summary of
prescribing information for

Lidone™ (molindone hydrochloride)

DESCRIPTION — LIDONE (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

LIDONE is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4(5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

ACTIONS — LIDONE (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditional response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, LIDONE antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, LIDONE exerts its effect on the ascending reticular activating system.

Human metabolic studies show LIDONE (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24 to 36 hours. There are 36 recognized metabolites with less than 2 to 3% unmetabolized LIDONE being excreted in urine and feces.

INDICATIONS — LIDONE (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS — LIDONE (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy: Studies in pregnant patients have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats oral dose —
20 mg/kg/day — 2 weeks, no adverse effect
40 mg/kg/day — 2 weeks, no adverse effect

Pregnant Mice oral dose —
20 mg/kg/day — 9 days, slight increase resorptions
40 mg/kg/day — 9 days, slight increase resorptions

Pregnant Rabbits oral dose —
5 mg/kg/day — 12 days, no adverse effect
10 mg/kg/day — 12 days, no adverse effect
20 mg/kg/day — 12 days, no adverse effect

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of LIDONE (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of LIDONE (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

PRECAUTIONS — Some patients receiving LIDONE (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving LIDONE. Caution should be exercised where increased activity may be harmful.

LIDONE does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, convulsive seizures have been reported in a few instances.

LIDONE has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS

CNS Effects — The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological Extrapyramidal Reactions — Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia — Motor restlessness may occur early.

Parkinson Syndrome — Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome — Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System — Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological — There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with LIDONE may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects — Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Lactation associated with LIDONE therapy has not been reported. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with LIDONE.

Cardiovascular — Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological — Lens opacities and pigmentary retinopathy have not been reported where patients have received LIDONE (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with LIDONE.

Skin — Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with LIDONE usage alone.

LIDONE (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when LIDONE is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia — Although rarely reported with LIDONE (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION — Initial and maintenance doses of LIDONE (molindone hydrochloride) should be individualized, and the minimal effective dose should be employed. Elderly and debilitated patients should be started on lower dosage.

DOSAGE SCHEDULE, BASED ON SEVERITY OF SYMPTOMATOLOGY

1. Mild — 5 mg three or four times a day; an increase to 15 mg three or four times a day may be required.
2. Moderate — 10 mg three or four times a day; an increase to 25 mg three or four times a day may be required.
3. Severe — daily dosage as high as 225 mg may be required.

DRUG INTERACTIONS — Potentiation of drugs administered concurrently with LIDONE (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when LIDONE is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE — Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of LIDONE (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of LIDONE (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by LIDONE in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized LIDONE from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of LIDONE is excreted unmetabolized in the urine.) However, poor response of the patient may justify use of these procedures.

While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized LIDONE in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents (i.e., Artane*, Cogentin*, Akineton*).

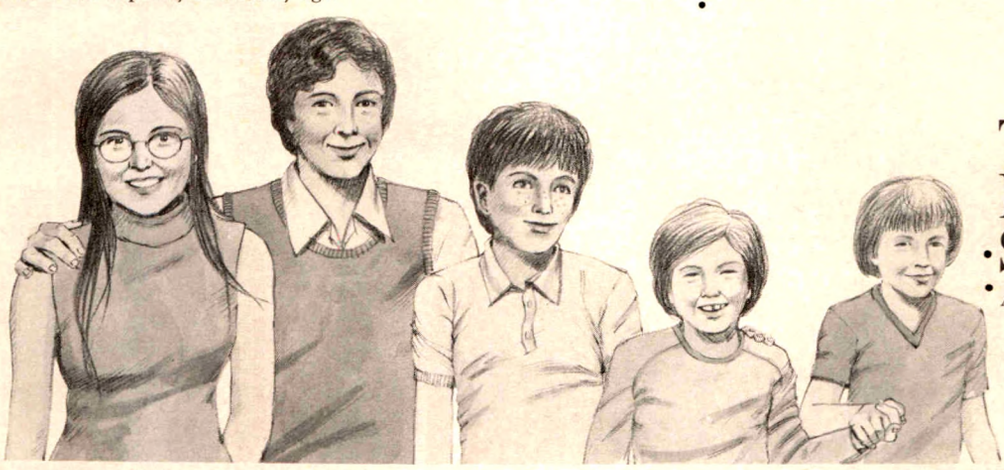
Flexibility is our forte: The Brown Schools

Because we maintain great flexibility at all three of our treatment centers, each resident follows an individualized plan of treatment, training, education and care prescribed for that resident alone.

And we believe that residential treatment conducted in this highly individualized manner still is the most effective treatment for many. Our large, experienced staff is skilled in the treatment of children, adolescents and adults with learning disabilities, neurological impairment, mental retardation or emotional disturbance.



Our three treatment centers are geographically separated to provide the appropriate residential milieu, yet close enough that residents benefit from the comprehensive training and expertise of the entire staff. All three are psychiatrically oriented, so that we are prepared to treat emotional disturbance in persons of any intellectual capacity and of any age.

FROM BUTTERWORTHS:

FOUNDATIONS OF BIOCHEMICAL PSYCHIATRY

by David S. Segal, PhD, Department of Psychiatry, University of California, San Diego; Joel Yager, MD, Department of Psychiatry, University of California, Los Angeles; John L. Sullivan, MD, Department of Psychiatry, Duke University.

Foundations relates recent and contemporary research in biochemical determinants of behavior to clinical manifestations and therapy. It presents a heuristic survey of drug and brain mechanisms, discussions of biochemical correlates of affective disorders, schizophrenia, anxiety, Parkinson's Disease, and alcoholism; and considers the pros and cons of orthopsychiatry. The authors have selected representative original articles, to which they have added their own discussion to provide continuity.

CONTENTS:

Introduction to Fundamental Concepts; Schizophrenia; Affective Disorders; Neurosis; The Hyperactive Child Syndrome; Alcoholism; Psychoendocrinology; References; Glossary; Index.

"They have fleshed out the chemical bones of biological psychiatry with well chosen clinical material . . ." — Arnold J. Mandell, Chairman, Department of Psychiatry, University of California, San Diego. 346 pages, $19.95

One less concern for your patient with insomnia

The psychologically disturbed patient may be especially vulnerable to insomnia—and excessively preoccupied with it when it occurs. For the patient who would benefit from a hypnotic, consider the adjunctive use of Dalmane (flurazepam HCl), a benzodiazepine proved to provide specific relief of insomnia in sleep laboratory subjects and in psychiatric patients.

Proved in the sleep research laboratory in chronic insomniacs: 28 nights of insomnia relief without increasing dosage[1,2]

Dalmane is the only available hypnotic agent proved in sleep laboratory studies to be effective beyond the first two weeks, and still effective after 28 nights of administration. This continued effectiveness was demonstrated in an original 47-night study[1] and confirmed by another.[2] Insomnia is usually transient in most patients, and Dalmane is generally not necessary or recommended for longer than a few nights. However, in patients undergoing psychotherapy, adjunctive use of a hypnotic may enhance progress by reducing preoccupation with insomniac symptoms related to the psychological disturbance.[3]

Proved clinically on the psychiatric service: Prompt sleep, fewer nighttime awakenings and longer sleep for patients with insomnia[4,5]

Dalmane 30 mg administered *h.s.* for 7 nights improved sleep induction, reduced nighttime awakenings and increased total sleep time, in a controlled clinical study among 49 psychiatric patients. Objective findings (bed-check records) and subjective patient estimates agreed[4] (see next page for results).

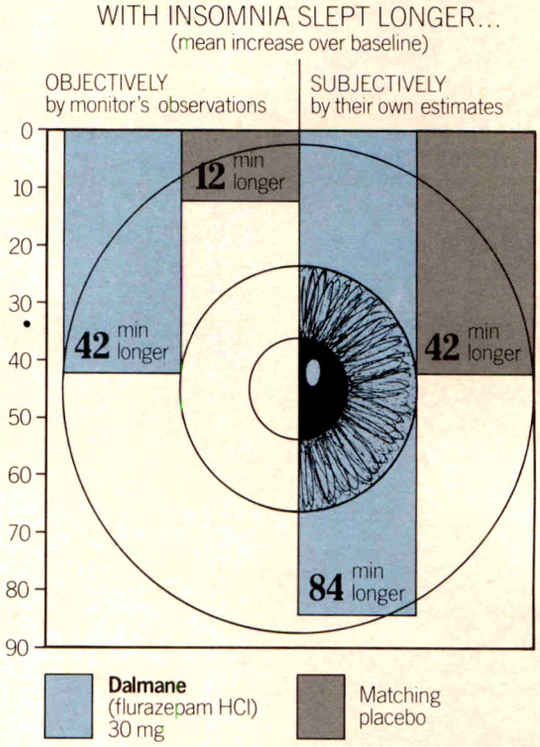
Proved over time: the relative safety of Dalmane (flurazepam HCl)

Dalmane has an excellent safety record;[5] patients generally tolerate it well, and seldom experience morning "hang-over." The usual adult dose (30 mg *h.s.*) remains effective from night to night without increasing dosage. To help preclude oversedation, dizziness or ataxia in the elderly or debilitated, prescribe 15 mg *h.s.* initially—a dosage proved effective[6] in elderly patients with insomnia.

because patient safety is of equal concern

Dalmane®
(flurazepam HCl) IV

One 30-mg capsule *h.s.*— usual adult dosage (15 mg may suffice in some patients).
One 15-mg capsule *h.s.*— initial dosage for elderly or debilitated patients.



ROCHE

Please see following page for a summary of product information.

Effective for insomnia encountered in psychiatric practice

Dalmane®
(flurazepam HCl)

- **objectively effective in the sleep research laboratory**
- **clearly effective in hospitalized psychiatric patients with insomnia**
- **consistently effective in adult insomniacs of all ages, including the elderly**
- **subjectively effective, with high patient acceptance and little morning "hang-over"**

(See previous page for discussion of study.)

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).

Usage in Pregnancy: **Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane, a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated, limit initial dosage to 15 mg to preclude oversedation, dizziness and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies. Periodic blood counts and liver and kidney function tests are advised during repeated therapy. Observe usual precautions in presence of impaired renal or hepatic function.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect. *Adults:* 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

THERAPEUTIC DISCOURSE

PSYCHOTHERAPY AS CONVERSATION

By WILLIAM LABOV and DAVID FANSHEL

This detailed study of the verbal interactions in fifteen minutes of a therapeutic session—from a long-term treatment of a young woman with anorexia nervosa—develops a comprehensive method for the analysis of conversations and provides insight into what actually takes place in therapeutic conversations. Linguistic analysis connects *what* is said and *how* it is said to the speech acts—supports, defenses, and retreats—that provide the basic coherence of conversations. This exploration of deeper layers of transaction lying beneath surface behavior reveals how patients in therapy resist the insights which would heal them.

CHARLES C THOMAS · PUBLISHER

PSYCHOTHERAPY FOR WOMEN: Treatment Toward Equality *edited by* **Edna I. Rawlings,** *Univ. of Cincinnati, Cincinnati, Ohio, and* **Dianne K. Carter,** *Univ. of Iowa, Iowa City. (22 Contributors)* Written and edited entirely by feminist therapists, this book provides constructive, alternative approaches to what the authors consider to be inadequate psychotherapeutic treatment of women today. Areas examined and developed include assertion training, careers, therapy for lesbians, social action and feminist therapy. Addressing both theoretical and applied issues, this important and provocative treatise will be a valuable resource for all psychotherapists and counselors who have women clients and for feminists who are reevaluating traditional approaches to psychotherapy. *'77, 500 pp. (6 3/4 x 9 3/4), 10 il., 16 tables, $17.50*

PSYCHIATRIC PROBLEMS IN OPHTHALMOLOGY *edited by* **Jerome T. Pearlman,** *UCLA School of Medicine, Los Angeles;* **George L. Adams,** *Baylor College of Medicine, Houston, Texas; and* **Sherwin H. Sloan,** *UCLA School of Medicine, Los Angeles. (11 Contributors)* A number of specific ophthalmological problems and topics related to emotional and psychiatric difficulties are presented in this unique, ground-breaking volume. The first chapter is an illustrated account of "The Eye and 'I' " in ancient and modern times. This is followed by discussions of reactions to the loss of sight, eye symptoms with no organic disease, stress and strabismus, and the psychiatric referral of visually handicapped patients. Helpful diagnostic and management ideas for children hospitalized with strabismus, black patch psychosis, status medicamentosus, and factitial eye problems are also presented. *'77, 180 pp., 29 il., 4 tables, $12.50*

RAPE INTERVENTION RESOURCE MANUAL *compiled and edited by* **Patrick Mills,** *Marietta College, Marietta, Ohio. Contributions by* **Lee Sachs.** This comprehensive manual offers guidelines for the operation of a crisis intervention center and the means of assessing the need for such a center in a particular locale. The text notes considerations in establishing a center and provides necessary material on the selection, training and evaluation of the rape crisis intervener so as to ensure effective and sensitive support to the sexual assault victim. Psychological, legal and medical aspects of intervention for both children and adults are discussed. Concerned citizens, law enforcement personnel, psychologists, paraprofessionals, social workers, and medical personnel will all profit from this valuable and informative book. *'77, 300 pp., 11 tables, $14.75*

THE HYPERACTIVE CHILD IN THE CLASSROOM *by* **Frank P. Alabiso,** *Milton Robinson and Associates, Springville, New York, and* **James C. Hansen,** *State Univ. of New York, Buffalo.* This comprehensive text presents an in-depth study and evaluation of the current literature on hyperactivity, and an overview of the hyperactive child in the classroom. The primary characteristics of hyperactivity — attention-distractibility, impulsiveness, cognitive dysfunctions, and activity level — are described individually, followed by an evaluation of treatment modalities. Major emphasis is placed on understanding the primary characteristics as separate behaviors subject to the principles of learning theory, while treatment of the condition is described in terms of reinforcement strategies with recommendations for implementation in the classroom. *'77, 336 pp., 10 il., $15.75*

SENSORY ISOLATION AND PERSONALITY CHANGE *compiled and edited by* **Mark Kammerman,** *Labyrinth Corporation, Beverly Hills, California. (13 Contributors)* The burgeoning study of sensory isolation and its potential applications are the foci of this monograph. World-renowned authorities in experimental psychology and psychiatry have contributed their thoughts and research on the status of experimental sensory isolation and have assessed its potential as a tool for personality change. The effects of sensory deprivation in both bed confinement and water suspension isolation are detailed, as are the uses of sensory isolation as a method of exploring the unconscious mind. Anyone interested in the future of psychotherapy, behavior change and knowledge of the self will want to read this book. *'77, 324 pp., 2 il., 39 tables, $12.75*

PSYCHIATRIC DRUGS FOR THE NON-MEDICAL MENTAL HEALTH WORKER *by* **William Goldsmith,** *Brentwood V. A. Hospital, Los Angeles.* Non-medical mental health personnel who work with patients receiving psychiatric medication are the people for whom this customized approach to psychotropic drugs is intended. Social workers, psychologists, paraprofessionals, counselors, therapists and students will find important data on anatomy, physiology and the biochemistry of psychiatric drugs and their effects on the patient. The basics of drug usage, including administration, metabolism, mechanisms of action and possible side-effects of phenothiazines, antidepressants, lithium, the minor tranquilizers, barbiturates and stimulants are all covered in detail. In keeping with the non-medical perspective of the book, unnecessary concepts and unfamiliar terminology have been omitted in order to concentrate on those aspects which are crucial to an understanding of the subject. *'77, 188 pp., 27 il., 7 tables, $11.50*

GROUP COUNSELING AND GROUP PSYCHOTHERAPY WITH REHABILITATION CLIENTS *edited by* **Milton Seligman,** *Univ. of Pittsburgh, Pittsburgh, Pennsylvania. (18 Contributors)* The most authoritative and most recent information on theoretical considerations, practical knowledge, research and specialized clinical skills is provided. Group work is discussed in relation to drug and alcohol abusers, the disadvantaged, stroke patients, the physically disabled, those with sensory impairments, the mentally retarded, the terminally ill, and public offenders. Topics include the peer self-help phenomenon, funding priorities, current trends in graduate training programs, and processes that characterize the conduct of most groups. *'77, 352 pp., 1 il., 7 tables, cloth-$16.50, paper-$12.75*

MUSIC AND THE BRAIN: Studies in the Neurology of Music *edited by* **Macdonald Critchley,** *National Hospital for Nervous Diseases, and* **R. A. Henson,** *The London Hospital, both of London, England. Foreword by* **Sir Michael Tippett.** *(22 Contributors)* This book deals with neurological aspects of musical experience. The first part is devoted to such topics as hearing, genetics, movement, the nervous control of voice production, psychology of musical talent, musical memory, synesthesia, and brain anatomy and physiology as related to music. The second section contains contributions on musicogenic epilepsy, mental illness in composers, neurological illness in performing musicians, deafness, occupational palsies, and music therapy. Neurologists and psychiatrists, of course, will find this book extremely interesting, but it will also appeal to anyone whose interest in music extends beyond the composer's notes. *'77, 476 pp., 59 il., 6 tables, $29.50*

Activity, Recovery, Growth

The Communal Role of Planned Activities

By JOAN M. ERIKSON
with DAVID and JOAN LOVELESS

An account of an activities program developed by Joan Erikson at the Austen Riggs Center, a small private institution for the emotionally disturbed. "An excellent work...should be of great interest to professionals involved in the hospital care and aftercare of the mentally ill and to others in the mental health disciplines as well as to medical students and students in various allied health fields...well written, concise, and practical." —*American Journal of Psychiatry* Illustrated with photographs. $10.95

Doing Better and Feeling Worse

Health in the United States

Edited by JOHN H. KNOWLES, M.D.

A group of twenty doctors, economists, political and social scientists were asked by the Rockefeller Foundation to examine the current state of health care. Their findings provide penetrating insights into the many issues—and consider the form a viable national health policy should take.
$9.95 cloth, $3.95 paper

The Complete Psychological Works of Sigmund Freud

The Standard Edition

Translated and edited by JAMES STRACHEY

The twenty-four volume set of the Standard Edition of the complete psychological works of Sigmund Freud contains the whole of Freud's published writings. The primary aim of the translations was the rendering of Freud's meaning with the greatest possible accuracy but with considerations of style as well. The translations, editorial commentaries, critical apparatus, indexes, and bibliographies make the Standard Edition an unrivalled source of reference for specialist, scholar, and student. $350.00 the set

THE COMPLETE WORKS OF SIGMUND FREUD

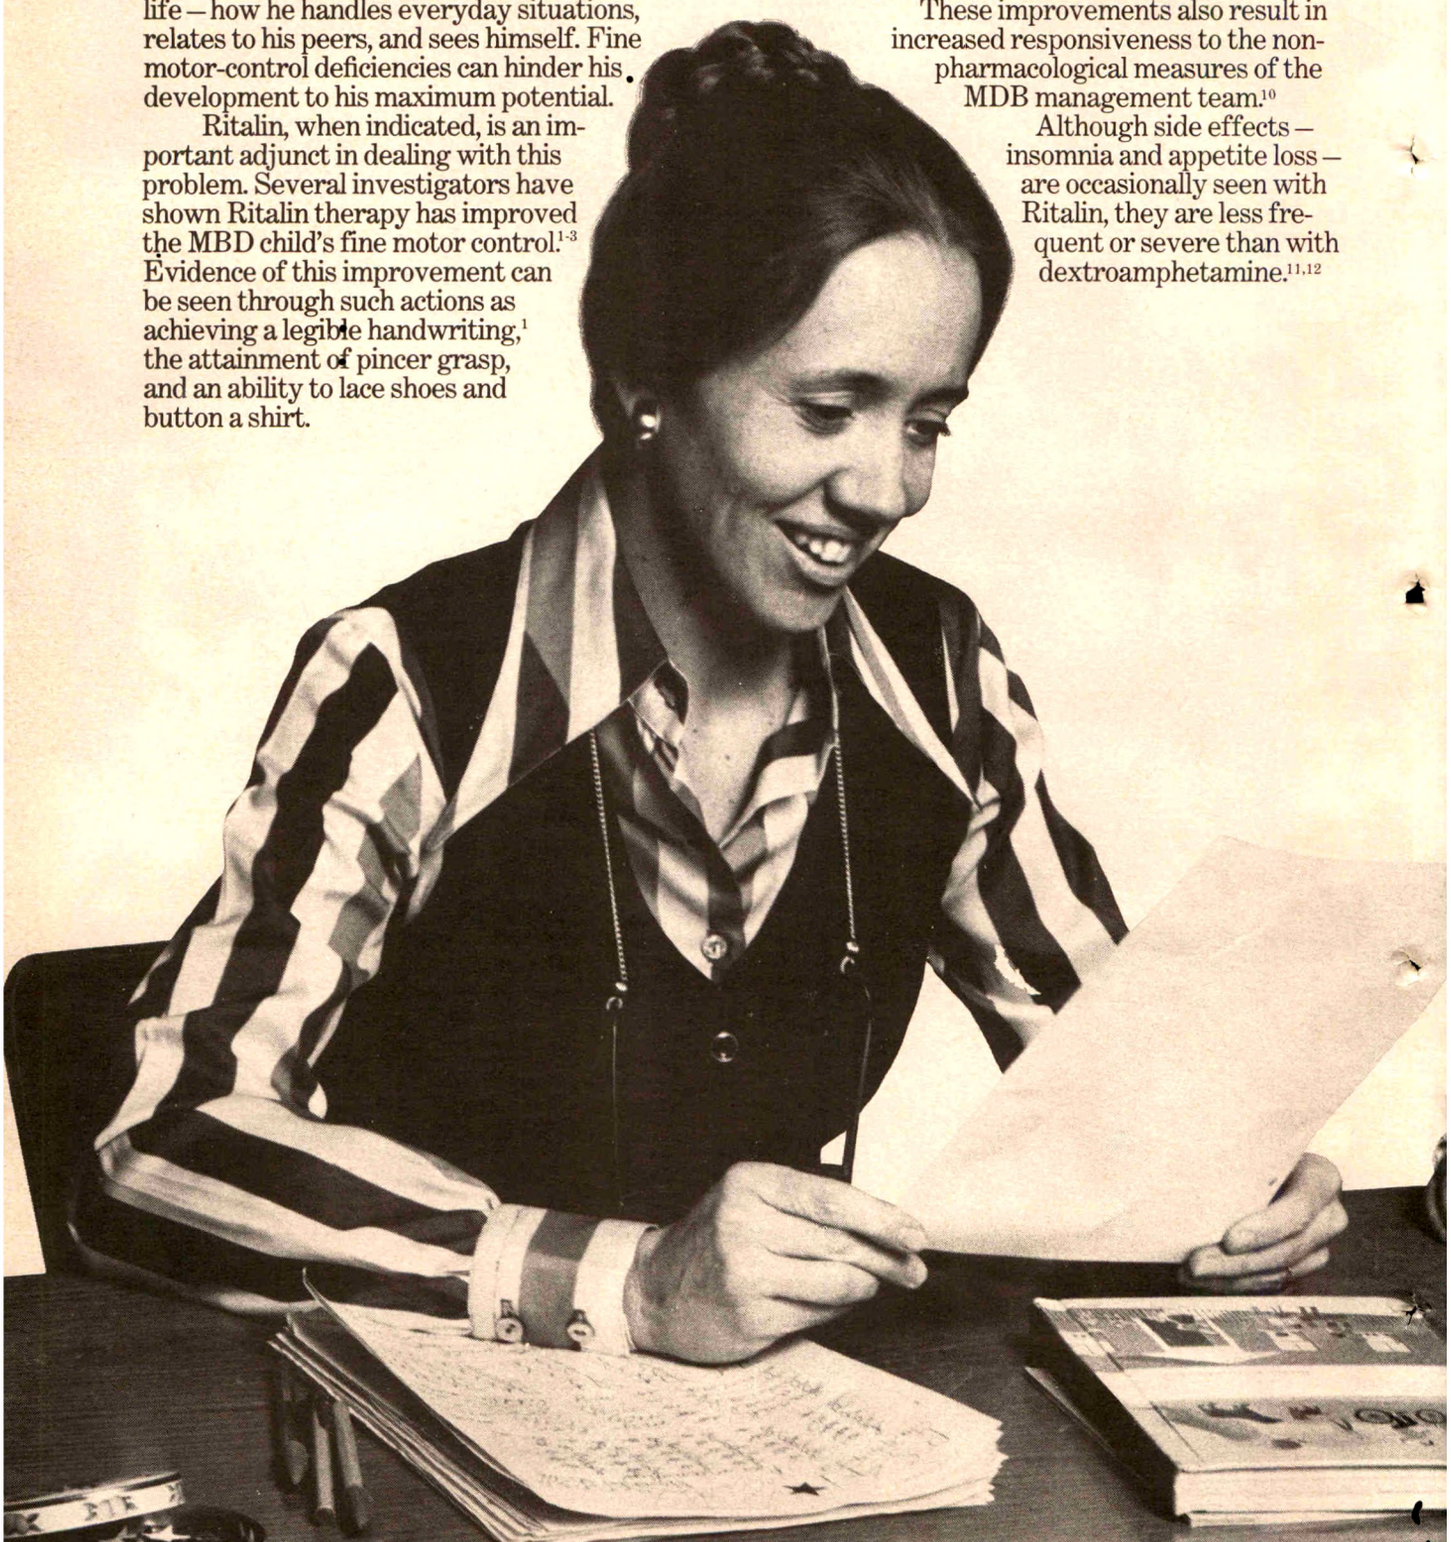
W.W. NORTON & COMPANY, INC., 500 Fifth Avenue, New York 10036

"How wonderful! Andy's handwriting no longer looks

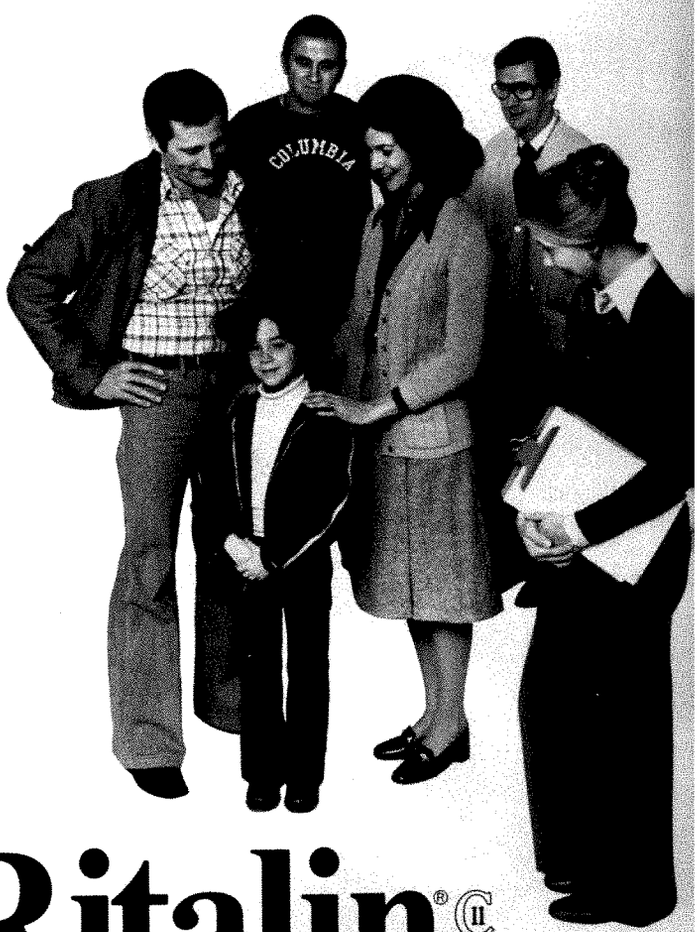


Fine motor-control deficiencies are often of concern to both the family and the teacher of an MBD child. Among these deficiencies are an inability to properly hold a pencil, an inability to grasp or release objects, and poor writing skills. This condition can affect the MBD child's daily life – how he handles everyday situations, relates to his peers, and sees himself. Fine motor-control deficiencies can hinder his development to his maximum potential.

Ritalin, when indicated, is an important adjunct in dealing with this problem. Several investigators have shown Ritalin therapy has improved the MBD child's fine motor control.[1-3] Evidence of this improvement can be seen through such actions as achieving a legible handwriting,[1] the attainment of pincer grasp, and an ability to lace shoes and button a shirt.

Based on controlled studies and clinical experience, Ritalin has proved itself to be a drug of choice for MDB.[4,5] In over 12 years of use, Ritalin has demonstrated the ability to significantly reduce hyperactivity,[6-8] distractibility,[2,6,9] and aggressiveness[6] in the MBD child.

These improvements also result in increased responsiveness to the non-pharmacological measures of the MDB management team.[10]



Although side effects – insomnia and appetite loss – are occasionally seen with Ritalin, they are less frequent or severe than with dextroamphetamine.[11,12]

like hen scratchings"

Therapy with Ritalin should be undertaken only after a medical diagnosis of MBD has been made. Dosage should be periodically interrupted. Often these interruptions reveal some "stabilization" in the child's behavior even without medication. In some MBD children they permit a reduction in dosage and eventual discontinuance of drug therapy.

Only when medication is indicated

Ritalin® (methylphenidate) C II

An effective member of the MBD management team

Please turn page for brief prescribing information.

CIBA

Ritalin® hydrochloride
(methylphenidate hydrochloride)
TABLETS

INDICATION
Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)
Special Diagnostic Considerations
Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.
Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.
Drug treatment is not indicated for all children with MBD. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS
Marked anxiety, tension, and agitation, since Ritalin may aggravate these symptoms. Also contraindicated in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS
Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.
Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain and/or height) has been reported with long-term use of stimulants in children. Therefore, children requiring long-term therapy should be carefully monitored.
Ritalin should not be used for severe depression of either exogenous or endogenous origin or for the prevention of normal fatigue states.
Ritalin may lower the convulsive threshold in patients with or without prior seizures; with or without prior EEG abnormalities, even in absence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. If seizures occur, Ritalin should be discontinued.
Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.
Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions
Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors. Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy
Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence
Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.
Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS
Patients with an element of agitation may react adversely; discontinue therapy if necessary.
Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS
Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include: hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.
In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION
Children with Minimal Brain Dysfunction (6 years and over).
Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.
If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.
Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is either temporarily or permanently discontinued.
Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED
Tablets, 20 mg (peach, scored); bottles of 100 and 1000.
Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.
Tablets, 5 mg (pale yellow); bottles of 100, 500, and 1000.

CIBA

The American Psychiatric Association announces publication of two volumes reporting the Conference on Education of Psychiatrists

held at Lake of the Ozarks, Missouri, June 9-15, 1975. Organized by the A.P.A. in cooperation with the American Academy of Child Psychiatry, the American Association of Chairmen of Departments of Psychiatry, and the American Association of Directors of Psychiatric Residency Training.

1. PSYCHIATRIC EDUCATION: PROLOGUE TO THE 1980's, Library Bound, 544 pages, $15.00.

This is a substantive, highly readable, report of the Conference, written by Anne H. Rosenfeld with an Editorial Board comprising: Ewald W. Busse, M.D., Chairperson of the Conference, Walter E. Barton, M.D., Bernard Holland, M.D., Donna Norris, M.D., Melvin Sabshin, M.D., Jeanne Spurlock, M.D., and Robert L. Robinson, M.A. (Staff Consultant).

The volume contains ten chapters covering the topical structure of the Conference: Goals and Values; Competence, Evaluation, and Quality Control; The Resident; Faculty; Educational Methods: Means in the Service of Ends; The Program Environment; Research; The Economics of Residency Training; Psychiatry in Its Social Context; and Retrospect and Prospect. It also contains nine appendices describing the organization of the Conference and its participants, together with selected model programs and related informational materials of value.

2. THE WORKING PAPERS OF THE 1975 CONFERENCE ON EDUCATION OF PSYCHIATRISTS Paper bound, 432 pages, $12.50.

Sixty two leading psychiatric educators served on seven preparatory commissions, one for each of seven topic areas, and prepared advance working papers as a basis for Conference deliberations. The topics and Commission Chairpersons were: Social Issues and Needs (James N. Sussex, M.D.); Goals and Objectives (Morton F. Reiser, M.D.); The Resident (David R. Hawkins, M.D.); Content, Methodology, Faculty and Environment (Milton Greenblatt, M.D.); Research (Daniel X. Freedman, M.D.); Economics (Herzl Spiro, M.D.); Evaluation and Quality Control (Eric Pfeiffer, M.D.). The Chairpersons, together with the Conference Chairperson, served as the Editorial Board for this volume.

Papers commenting on the reports of the commissions, published here for the first time, were presented at the Conference by Melvin Sabshin, M.D., Eugene B. Brody, M.D., Jeanne Spurlock, M.D., Jack R. Ewalt, M.D., Robert J. Stoller, M.D., James R. Comer, M.D., and Bernard Holland, M.D.

IN DEPRESSIVE NEUROSIS

ANXIETY

OFTEN ACCOMPANIES DEPRESSION

In 14 double-blind studies, of 339 patients with depressive neurosis who received Mellaril (thioridazine) over half had measurable relief within one week. Relief of the anxiety component was seen in 54.6% (185 of 339 patients) within the first week; relief of the depressed-mood component was seen in 53.4% (181 of 339 patients); relief of insomnia secondary to depression was seen within the first week in 50.2%, or 132 of the 263 patients with this symptom; and overall improvement was seen in 51.3% (174 of 339 patients) in the first week and in 86.4% (293 of 339 patients) by the end of the fourth week.

The most common side effects are drowsiness and dry mouth. Mellaril (thioridazine) is not habituating and usually does not cause euphoria or undue sedation. (The physician should, however, caution patients against participating in activities which require complete mental alertness, e.g., driving.)

in short-term therapy of moderate to marked depression
with variable degrees of anxiety in patients with depressive neurosis

MELLARIL® (THIORIDAZINE)

TABLETS: 10 mg, 15 mg, 25 mg, and 50 mg thioridazine HCl, USP

RESULTS OFTEN SEEN IN A WEEK

For Brief Summary, please see following page.

in short-term therapy of moderate to marked depression with variable degrees of anxiety in patients with depressive neurosis

MELLARIL®
(THIORIDAZINE)

RESULTS OFTEN SEEN IN A WEEK

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient. In adults with depressive neurosis the usual starting dosage is 25 mg t.i.d. and the dosage ranges from 10 mg b.i.d. to q.i.d. in milder cases to 50 mg t.i.d. or q.i.d. for more severely disturbed patients; the total daily dose ranges from 20 mg to a maximum of 200 mg.

ROBERT W. GIBSON, M.D.

Presidential Address: A Profession Worthy of the Public Trust

BY ROBERT W. GIBSON, M.D.

THE THREEFOLD escalation of health care expenditures from 1965 to 1975 has prevented the United States from making good on the commitment that adequate health care is a right. Government leaders, third-party payers, and the consumer, responding to inflationary pressures, have served notice that the amount and allocation of resources—dollars, facilities, personnel, and supplies—will be contingent on the ability of those of us who provide care to demonstrate that treatment services not only are effective but are delivered efficiently.

The leadership role of health care professionals has steadily eroded. Government planners and managers are setting health policy and establishing priorities. In many instances they lack clinical experience, and sometimes they seem insensitive to the needs of the mentally ill. If we as mental health professionals fail to act, we will lose our ability to influence the quality and character of care provided to our patients.

Protestations of outrage may provide catharsis but are not enough. We must acknowledge that abuses do occur and that the health care delivery system has many flaws. Because health is influenced by many social forces, psychiatry interacts with a multitude of systems, making rational control difficult and complex.

But increased government regulation is not the solution; more often it is the problem. In my judgment it is our professional responsibility to strengthen our own systems of quality assurance, show that external regulation is only minimally necessary, and reaffirm the public trust. This is why I requested that the theme of this Toronto meeting be "Professional Responsibility and the Public Trust."

In this address I hope to demonstrate that: 1) while the national concern about increasing health care costs is valid, simply adding government regulation is *not* the solution—in fact, inappropriate regulation can cause many problems; 2) APA has moved into many new areas and has attempted to strengthen its activities in other areas so as to enhance prospects for a more rational and effective mental health care system; and 3) we recognize that a new level of accountability is expected of us and we stand prepared, through our peer review and related efforts, to show that we are equal to the challenge.

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977.

Dr. Gibson was 105th President of the American Psychiatric Association, 1976–1977. He is Medical Director, Sheppard and Enoch Pratt Hospital, Towson, Md. 21204.

THE PROBLEM OF RISING HEALTH COSTS

In 1976, total expenditures for health in the United States amounted to $139.3 billion, or $638 per person; these expenses claimed 8.6% of the gross national product, with 42.2% coming from tax dollars. These 1976 expenditures represented a 14% increase over fiscal year 1975, and inflation continues at close to 10% annually. At 8.6% of the GNP health care expenditures have a significant impact on the overall economy, and with over 42% of the funds coming from tax dollars the cost of health care has become a significant political issue and provides the government with enough leverage to control the system.

Alarmed by runaway costs, legislators are hedging on the original declaration that health care is a right. For example, the statement of purpose of the Health Planning Act (PL 93-641) stipulates: "The achievement of equal access to health care at a reasonable cost is the priority of the federal government." Equal access is now a priority, not a right; even that is conditional on "reasonable cost." The determination of what is a reasonable cost will be a political decision, not a medical decision.

National health insurance is still a significant political issue but is being pushed with less vigor because of concern about costs. Instead, the current government emphasis is on efforts to control and reshape the health care system and presumably to make it more efficient and cost effective.

For example, appropriations to assist health maintenance organizations are intended to promote organized systems of health care as opposed to individual private practice. Legislation authorizing Professional Standards Review Organizations is designed to increase participation by physicians in utilization review activities. The Health Planning Act establishes a network of local, state, and national citizen groups to plan, coordinate, and control health care resources. The Health Professions Educational Assistance Act of 1976 provides the mechanisms to control that most important of all health resources—trained personnel.

It appears that the strategy is to move cautiously on national health insurance until the various controls are in place and working effectively. This reflects the conviction of government planners that simply adding dollars and benefits will not improve the health of our nation. The message is plain. Payers, whether they be federal or state government or insurance carriers, will make resources available only to the degree that providers can demonstrate they can control these resources and use them effectively and efficiently. Evaluation and quality assurance are now preconditions that must be met before mental health benefits will be increased.

SPECIAL CHALLENGES FOR PSYCHIATRY

Satisfying such expectations of accountability is difficult for all segments of the health care industry. Regrettably, mental health is often singled out for special challenge while other types of care are not. Consider that the National Ambulatory Medical Care Services (NAMCS) estimates that in 1973–1974, visits to physicians numbered 14 million for colds, 18 million for back problems, 12 million for headaches, 12 million for fatigue, and so forth. Many of these conditions were probably psychosomatic, many were not amenable to definitive medical treatment, and outcome and cost benefit would be impossible to judge. But expenditures for such care are not challenged to the same degree as mental health services.

Some of the more difficult tasks confronting psychiatry are: 1) completion of valid outcome studies; 2) refinement of standards and criteria; 3) achieving a balance between humanistic concerns and cost effectiveness; and 4) preservation of confidentiality. Psychiatrists have not been derelict; as we interact with other social systems the increased exposure inevitably opens us to new challenges and new demands to justify our practice.

BUREAUCRATIC INTRUSIONS

The demands frequently take the form of bureaucratic intrusion seemingly to the point of harassment. A task force on regulation created by the Hospital Association of New York State to assemble information on the scope of the problem found that no less than 164 different regulatory agencies had some jurisdiction over hospitals in the state (1). Acknowledging that government has the right to regulate hospitals, the task force, in its study of the impact of regulation, wondered why 25 separate agencies must review hospital admitting procedures, why 33 agencies protect patients' rights, and why 31 agencies insure patients' safety. The task force found that during the past 10 years, while the total number of employees in the state health department went from 2,000 to 3,500, the number of accountants went from 2 to 170 and the number of attorneys went from 3 to 30. But the number of physicians declined from 69 to 60. The state's new austerity budget calls for 568 new regulatory positions in the department!

Most of the regulatory efforts are well intentioned. But unfortunately the controls overlap, are sometimes contradictory, and add to the cost of care. Preoccupation with these multiple requirements may distract mental health professionals from their main goal: providing high quality treatment services appropriate to the patient's need. In exasperation, staff protest that it has become more important to document that some arbitrary requirement has been met than it is to do something that will be really helpful to the patient.

Despite the heavy emphasis on reducing length of stay, an October 1976 report commissioned by the Department of Health, Education, and Welfare (2) estimated that utilization controls would reduce the cost of additional services under the American Medical Association's national health insurance proposal by $.3 billion (less than .2%) and under the Health Security Bill by $1.4 billion (only .7%). Regulation adds to costs through special reports, legal services, requirements for documentation, and the like. Beyond that comes the time of clinicians diverted from patient care as they are kept busy meeting the requirements. It would not surprise me if these activities add 5% to 10% to the health care budget. Surely our profession can develop a better system.

CONSEQUENCES OF REGULATION BY THIRD-PARTY PAYERS

The funding mechanism is seen as a tool to manage the health care system through planning, organizing, coordinating, staffing, motivating, and controlling. Although other nations have established a national health service under which the government owns the facilities, hires the personnel, chooses locations for dispensing care, and by taxation pays whatever costs are required, there appears to be no significant support in this country for such a solution. Instead, the approach will probably be one of voluntary participation by providers and possibly by consumers. More liberal benefits and coverage for participants will be strong inducements to consumers to seek care from those providers who are a part of the system. Government planners,

by reshaping the health care system, hope to overcome maldistribution of providers, inaccessibility of services, and inappropriate utilization of personnel.

A troublesome consequence is that as our health care system becomes more complex, the decision-making process is removed further and further from those providing direct patient care. Clinicians find it increasingly difficult to participate in top management decisions such as the allocation of resources and the setting of priorities.

Third-party payers, both government and private, have already gained strong control over the health care system. Under Medicare and Medicaid, government officials decide what benefits should be available, set standards for providers, and establish criteria for the services themselves. All national health insurance proposals contain schemes of economic incentives and disincentives to reshape the system.

The techniques used by large private health insurance carriers, such as the federal employees programs, provide insight into the way the funding mechanism can influence psychiatric care. Faced with escalating costs, insurance carriers have initiated claims review: a patient seeks help, a practitioner provides the service, a claim is submitted to the third-party payer, the claim is either paid or it is not. This last step establishes a crucial feedback to the system. As long as claims are paid, psychiatrists continue to provide services in accordance with their best clinical judgment.

Clinicians are disturbed when claims review leads to the denial of treatment for a particular patient. This is of grave concern to the patient, and the long-term consequences are even more serious. Professionals would in most cases continue to provide the services they deem medically necessary and appropriate without regard for payment. Nevertheless, decisions about payment over a period of time would undoubtedly exert an influence. Psychiatric care might evolve in a sequence akin to the process of the survival of the fittest, or perhaps it should be called "the survival of the most reimbursable." It could become a monstrous application of the behavior modification technique. Presumably those facilities and those practitioners who favored the kind of treatment supported by third-party payers would flourish, while the rest would languish.

There is no question that those who pay for care have the right to make determinations about the care. They are accountable for the expenditures of tax dollars in the case of government programs, the premiums of subscribers in the case of private insurance, or the fringe benefits in the case of a union or employer. There is nothing inherently wrong with using funding to better organize the health care system. The danger is that decisions will be based on standards and criteria that do not reflect the best professional opinion of practicing psychiatrists—that the requirements of administrators and managers will outweigh the needs of patients.

Increasing regulation and the growing demand for accountability disturb the professional because they challenge the basic concept that members of the profession are capable of self-discipline. Have we failed to maintain adequate standards of professional responsibility? Do our systems overlap so much that responsibility must be shared? Have professionals lost the public trust?

Many clinicians, particularly physicians, are so accustomed to society's sanction they are convinced that complete autonomy is a prerogative automatically granted with the professional degree. This is simply not true. Practice of a profession is not a right, it is a privilege—a privilege that must be earned and repeatedly reaffirmed by responsible action and behavior.

EXPANDED APA ACTIVITIES

I will return to this matter of professional responsibility shortly. But first I want to highlight for you a few of the extensive activities APA has undertaken recently to increase our level of participation in decisions that affect our profession and the quality of care given to our patients.

Government Relations

The Joint Commission on Government Relations, composed of members from each of the seven geographic areas, coordinates the legislative network of district branch representatives. Mr. Jay Cutler, an attorney who served as Minority Counsel to the U.S. Senate Health Subcommittee and the Alcoholism and Narcotic Subcommittee and more recently as Minority Counsel and Staff Director of the Senate Labor and Public Welfare Committee, has been appointed Special Counsel and Director of the expanded Office of Government Relations. The annual Institutes on Governmental Operations (the sixth was held in March) have helped district branch legislative representatives to become more knowledgeable and effective in their presentations to government leaders. The Joint Commission has developed 10 key principles dealing with private practice, continuing education, malpractice, primary care, PSROs, nonphysicians in NHI, pluralism in the health care system, professional responsibility for medical education, input into regulations, and accountability. Legislative proposals are continuously monitored, contacts with key Congressional leaders made, and testimony provided as needed.

President Carter has shown a special interest in mental health by appointing a Presidential Commission on Mental Health under the honorary chairmanship of Mrs. Rosalyn Carter. This commission has been charged with preparing a final report by April 1978 that will, among other things, project needs for dealing with emotional stress over the next 25 years, find ways to more efficiently treat the underserved mentally ill, identify the types of research and educational systems needed, and estimate the cost of programs and how financing should be divided among fed-

eral, state, and local governments and the private sector. This 20-person commission has a strong consumer majority, but among its membership are 3 psychiatrists: Allan Beigel, M.D., Mildred Mitchell-Bateman, M.D., and George Tarjan, M.D. There are 2 additional physicians, one of whom is closely allied to child psychiatry; the other has had considerable experience with drug abuse problems. Advisory groups dealing with a number of special areas are being appointed. APA will work quite closely with this commission.

Commission on Public Affairs

To back up our governmental activities through a strong base of public support, the Joint Commission on Public Affairs has begun to set up mechanisms to enable the Association to become more active in informing the general public about the psychiatric profession, to monitor public attitudes toward psychiatry, and to cooperate on a continuing basis with the media and other institutions that influence the public's view of psychiatry.

Some of the means for achieving these goals are: publication in the *American Journal of Psychiatry* of guidelines for psychiatrists working with the communications media, establishment of a roster of press contacts, formation of a public affairs network with representation in each of the district branches, a public opinion survey, identification of friends and advocates of psychiatry, responding to attacks on psychiatry, informing major networks of the APA position on televised violence, and a planned symposium for science writers in the late fall of 1977.

Commission on Standards of Practice

The Commission on Standards of Practice and Third-Party Payment has represented APA on issues concerning government programs and private insurance carriers. In 1974, when serious cutbacks in the Blue Cross and Blue Shield federal employees program and in CHAMPUS were threatened, the commission spearheaded an effort that preserved the psychiatric benefits in these programs. A dialogue has been maintained with various third-party payers concerning standards and criteria for care, procedures for reporting claims, and the claims review process. A joint task force of APA and the federal employees Blue Cross and Blue Shield program is revising guidelines to reflect professional judgments of psychiatrists; peer review will be incorporated into the review process of claims for psychiatric care. The commission and the APA's Medical Director have also been authorized by the Board of Trustees to enter into a contract to help CHAMPUS set up a retrospective review system regarding claims presented to CHAMPUS for payment. APA will be asked to identify psychiatrists willing to participate in this system (with reimbursement at a level comparable to their regular hourly rate) and to provide an educational program for the psychiatrists participating.

Peer Review

Peer review activities have been advocated by APA as the most appropriate way to meet demands for accountability. The Peer Review Committee has prepared *Model Screening Criteria to Assist Professional Standards Review Organizations* for the AMA PSRO manual and has published the *Manual of Psychiatric Peer Review*. Richard Dorsey, M.D., an APA member, has consulted with about 40 district branches over the past year, supplying assistance in the development of their peer review efforts. In March of this year a National Conference on Peer Review brought together third-party representatives, consumers, technical experts, and psychiatric leaders to further refine and develop the APA peer review system. It is anticipated that the proceedings of this conference will be published by early fall.

Interprofessional Relations

Differences among the major mental health professions—psychiatry, psychology, social work, and nursing—are being discussed and sometimes heatedly debated. *Advance*, published by the Association for the Advancement of Psychology, has repeatedly criticized the officers of the Board and the Assembly of the American Psychiatric Association. In an article headlined "No Peace in Our Time" (3), *Advance* objected to what they labeled the "Gibson Syndrome." In testimony on national health insurance before the House Interstate and Foreign Commerce Committee I had said, "In my judgment, the diagnosis and determination that services are medically necessary should be made by a physician, a psychiatrist."

Also, the Association for the Advancement of Psychology, in a complaint filed with the Federal Trade Commission, alleged: "The Joint Commission on Accreditation of Hospitals standards are nothing less than artificial and predatory barriers . . . imposed with no medical, social, or economic justification. . . . [This] effectively and systematically prevents hospital patients from exercising their free choice of attending therapist. . . . Indisputedly, psychiatrists benefit from this arrangement." The Federal Trade Commission, which is still considering this complaint, was provided with a point-by-point refutation of the allegations that was prepared by APA's legal counsel.

Changes in traditional staffing patterns, greater emphasis on the team approach, and shifts in the level and degrees of responsibility are evolving. APA is not against change as long as it is rational and there are sufficient safeguards to maintain the safety and quality of treatment. An Ad Hoc Committee on Professional Relations has met for almost 3 years with representatives from psychology, social work, nursing, and the Mental Health Association to define more precisely the areas of practice appropriate for each of these professions. The presidents and executive directors of the two APAs have also met to improve communication between our two associations. The mental health pro-

fessions are confronted by difficult questions. In articulating our positions scientific study is preferable to power politics. Considered judgment, restraint, and statesmanship are needed; our professional associations have an opportunity to work together collaboratively and responsibly.

Confidentiality

Concerning problems affecting the confidentiality of the doctor-patient relationship, I think we can be proud of the leadership that APA has provided in recent years. In a series of steps beginning with the Conference on the Confidentiality of Health Records held in Key Biscayne in November 1974, APA was able to organize 17 national organizations into forming the new National Commission on Confidentiality of Health Records in Washington, D.C. The commission, chaired by APA Past-President Alfred M. Freedman, is an action-oriented organization dedicated to coping more effectively with the growing threat to the confidentiality of health records implicit in the growth of third-party payments, "need to know" agencies, and computer technology.

Role Conflicts

We may also be pleased that after several years of effort, APA was able to conduct the first major conference on problems of "role conflicts in psychiatry" in cooperation with the Hastings Institute of Society, Ethics, and the Life Sciences. While we must be concerned and alarmed about the abuses of psychiatry and psychiatrists in other countries, it behooves us also to cast a questioning eye at our own practices in the service of patients, on the one hand, and institutions, on the other, in the complex roles we play in the military, in universities, in hospitals, in prisons, and in other institutional frameworks. The report of the Hastings conference, which will be published within the next several months, will go far to raise our consciousness about the philosophical, ethical, and socioeconomic aspects of this problem area. Also, at the request of APA an open forum will be held during the World Congress of Psychiatry meetings in Hawaii to deal with the use of psychiatry to control political dissent.

Commission on Judicial Action

Through its Commission on Judicial Action, APA has proven remarkably effective in monitoring federal Courts of Appeal and Supreme Court proceedings and in submitting amicus curiae briefs in cases that promise great positive or negative impact on the treatment of the mentally ill and our future as a profession. The resources we can put into this important area are of course limited and the legal costs high. However, we anticipate increased activity following the appointment last January of Mr. Joel Klein, a member of a Washington, D.C., law firm, as counsel; he will coordinate the activities of the commission and represent APA in its role as amicus curiae in cases selected by the commission.

Continuing Medical Education; Certification and Recertification

Continuing education requirements were voted by the APA membership in 1974; now we have to see that the system is fully implemented in a manner designed to help our members meet state licensure requirements as well as APA standards. For example, we are changing the format of our annual meeting to enable members to earn more continuing education credits than ever before. For those who are unable to attend the annual meeting, the Psychiatric Knowledge and Skills Self-Assessment Program will serve a similar purpose. We have also been collaborating with the AMA in its continuing education activities.

A rational plan for insuring the continuing competence of psychiatrists through certification and recertification programs is making headway under our auspices. While we are mindful of the heterogeneity of our membership, we see these efforts as a symbol of our strong commitment to meeting our professional responsibility.

ADVOCATES OF THE MENTALLY ILL

In these extensive activities our Association rarely has explicitly designated authority. No longer does the public automatically accept our opinions and recommendations in areas of professional expertise. We must rely on educative efforts, carefully reasoned professional opinions, and effective presentations and leadership.

As we have become more active we have—through our national officers, the Assembly of District Branches, the district branches themselves, and our Medical Director and Central Office staff—engaged in a myriad of activities that go far beyond the scope of medical practice and scientific inquiry. Although the main concern of APA continues to be the scientific advancement of psychiatry, we must use this knowledge to serve as advocates for the mentally ill.

Some APA members interpret our actions as "selling out to the enemy" and repudiating what they believe to be our professional prerogatives. They have a point; there *is* a delicate balance. But we must recognize that controls and regulatory authorities have already been established. We do not have absolute authority over the manner in which we perform professional tasks. We do not have complete control over the setting or conditions under which we practice. Militant refusal to become involved may succeed in some instances, but these victories are shortlived. Control of health care is no longer the professional prerogative of the physician. Health care, much like a public utility, belongs to the public.

The involvement of APA is not a passive accommodation. It is active, with particular emphasis on advocacy of the needs of patients. APA does represent the interests of its members, but it does so as a profession,

not as a trade association. There need be no fundamental conflict. Patients and psychiatrists share a common goal—adequate health care for the mentally ill. Patients want care to be accessible, appropriate, and timely. Psychiatrists want adequate resources to provide such care and the opportunity to practice their profession under conditions that are in the best interests of the patient.

A NEW LEVEL OF ACCOUNTABILITY

In this day and age of accountability it is unrealistic to think that any profession can retain total control over professional tasks. We can achieve significant influence only by active participation with government, the consumer, third-party payers, and allied professions. We have known this for years, but we must now recognize that the current climate is more complex and more demanding. In the interest of quality patient care, responsible professional action is essential.

Of high priority is the introduction of peer review into the systems used for claims review and quality assurance. Claims review conducted by third-party payers has many disadvantages: 1) clinical judgments are susceptible to financial pressures, 2) third-party payers seldom have the clinicians capable of adequate review, 3) standards and criteria are established by the payers and not the providers, 4) the criteria are not open to public scrutiny, and 5) the findings of such reviews may be used by third-party payers to change the basic contract agreements under which treatment is provided. In short, reviews conducted by those outside the profession are designed to control costs, not to improve the health care system. They become a constraint imposed upon the professional.

On the other hand, if psychiatrists are made a part of the review system: 1) clinical judgments will reflect current psychiatric concepts; 2) psychiatrists with specialized competence will conduct meaningful clinical studies; 3) standards and criteria will be established, refined, and modified by the profession; 4) the standards and criteria will be open to public scrutiny; 5) and the findings will be used to improve psychiatric care as well as to control abuse and unnecessary expenditures. Claims review will no longer be a constraint; it will become a part of our professional quality assurance system—a resource contributing to the improvement of mental health care.

Peer review further illustrates the need for participation at both the national level and the local level. At the national level the Association, supported by the Office of Peer Review, has developed guidelines, influenced legislation and regulations, carried the message to members of Congress, worked with the major insurance carriers, and provided consultation to district branch peer review committees. But the actual review by peers must be carried out at the local level in accordance with standards and criteria developed for the area. Agreements with local carriers, the review of cases, and corrective actions must be done by district branch committees. The strength and the effectiveness of the American Psychiatric Association is based on the active participation of the total membership.

These are challenging times. A new level of accountability is expected from all professions. But this is not the problem. The danger is in allowing leadership to slip away from the mental health professions. This would be catastrophic, because the essence of professionalism is control over both the performance of professional tasks and the setting and conditions under which such tasks are performed. Individually and collectively we must demonstrate through responsible action that psychiatry is a profession worthy of the public trust.

Response to the Presidential Address

BY JACK WEINBERG, M.D.

THE BRITISH PLAYWRIGHT Robert Bolt, in his play *A Man for All Seasons*, has a character called Common Man. After the final and peculiar rites of passage at the Tower of London devised for that Uncommon Man, Thomas More, who chose to be accountable to his conscience rather than to his monarch, this Common Man (who not surprisingly is the executioner) comes forward and ends the play with the following words,

> I'm breathing . . . are you breathing too? It's nice, isn't it? . . . It isn't difficult to keep alive, friends—just don't make trouble, or if you must make trouble, make the sort of trouble that's expected. Well, I don't need to tell you that. Good night. If we should ever bump into one another, recognize me. (1, p. 162)

The message is clear: March unquestioningly to the drum of authority even at the sacrifice of principles and loyalty to one's profession so that common man's axe may be stayed, so that one may be able to breathe, if not to live.

Dr. Gibson has today detailed for us the troubles, expected and unexpected—some of our making, most not—that we must face. In his characteristic cool and unflappable manner, and in keeping with the theme of this annual meeting and its much more civilized rites of passage, he has pointed out to us the forces in control of our destiny and our adaptive responses.

Many of the problems we encounter are not so much in the hands of our Association, its leadership and its staff, as in the hands of outside forces and bureaucracies whose machinery we are unable to budge. Also involved are those in our sister disciplines who attempt to vitiate our efforts to maintain our integrity as psychiatrists who bring to our therapeutic efforts the uniqueness of a medical education.

Our members expect our Association's leadership to help promote and maintain public trust in our profession and its accountability. Dr. Gibson has demonstrated admirable leadership in that direction in the face of criticism from within and without. Much has been achieved during his competent stewardship. However, it would be unseemly of him to resolve everything and leave no task undone for his successor. Accountability is an ever-continuing process. Accountable to the public and its agencies we are and we shall be, as our efforts in that direction indicate.

As the incoming President of our Association, may I, however, state that I am even more concerned about being accountable to our patients and our profession. I am certain that those are the sentiments of most of you. We find ourselves in the position of another character, in a tale told by Elie Wiesel,

> One of the Just Men came to Sodom, determined to save its inhabitants from sin and punishment. Night and day he walked the streets and markets preaching against greed and theft, falsehood and indifference. In the beginning people listened and smiled ironically. Then they stopped listening; he no longer even amused them. The killers went on killing, the wise kept silent, as if there were no Just Men in their midst.
>
> One day a child, moved by compassion for the unfortunate preacher, approached him with these words: "Poor Stranger, you shout, you expend yourself, body and soul; don't you see that it is hopeless?"
>
> "Yes, I see," answered the Just Man.
>
> "Then why do you go on?"
>
> "I'll tell you why. In the beginning I thought I could change men. Today I know I cannot. If I still shout today, if I still scream, it is to prevent man from ultimately changing me." (2, pp. 94–95)

Why is it, then, that I wish to shout, that I wish to be heard, that I wish to preclude the changing of us? It is simply because I want to warn against the triumph of expediency over purpose, of structure over function. Our purpose is clear and unvarying: it is to alleviate emotional suffering, even though we are fully cognizant that we are confronted by the human condition, with its unsurpassed inventiveness to mobilize pain. There is no substitute for the skillful, holistic diagnosis and the careful and meaningful treatment of the ill.

While I readily see the necessity for examining our structure and modifying it to promote more efficient function, I have been concerned that in pursuing structural change, function may be neglected. Our organizational functions, as I see them, are triple in nature: scientific, social, and guild concerns.

1. The scientific function of our Association is clearly stated in our Constitution. I see ourselves assiduously engaged in the realization of these objectives. Although our efforts seem to be overshadowed by other concerns, these are the primary and continuing priorities.
2. In regard to the social function, I am reminded of

Read at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977.

Dr. Weinberg is 106th President of the American Psychiatric Association. He is Director, Illinois State Psychiatric Institute, 1601 W. Taylor St., Chicago, Ill. 60612, and Professor of Psychiatry, Rush Medical College and Abraham Lincoln School of Medicine, University of Illinois, Chicago.

the words of the great Rudolf Virchow (1821–1902), who observed that if medicine were ever to fulfill its great ends, it must enter into the larger political and social life of our time; it must indicate the barriers that obstruct the normal completion of the life cycle and remove them (3). No more eloquent statement needs to be made in any period in which medicine and psychiatry (as a branch of it) profess to be concerned with the health of its citizens. Everything that ever happens in the world in some way affects the emotional well-being of our people. Medicine, properly practiced, is not meant only to alleviate suffering; it should also vigorously pursue methods to prevent the occurrence of illness and preclude its recurrence. It is not only as citizens that we should be concerned with such issues as poverty, discrimination, war, and degradation of the human spirit. As conscientious physicians we should see in all of these ecological factors dangerous phenomena affecting the psyche, the soul—creating patients out of a healthy population. Illnesses are processes out of synchronization with oneself and one's environment. Health, after all, is the ability to control and command internal and external events that affect our life and affect behavior.

If we ourselves fail to recognize the validity of all this, certainly the world about us, including our social institutions, tends to ascribe these obligations to us. We are called upon to alleviate all social ills, not because we have been so vociferous regarding our omnipotence but rather because society at large believes that we may have solutions which transcend commonsense.

While we do not have all the answers, we must not avoid the obligation to continually search for solutions and actively participate in efforts to improve the human condition.

3. In regard to guild functions, I for one do not become disturbed when we are accused that APA has such functions. I believe that we should use every legitimate effort to oppose, educate, and convince those who, out of misinformation, mischief, or intent would cripple our discipline by restrictive legislation and regulatory measures. We must define ourselves and our areas of competence.

We are engaged in a struggle with other professionals in the mental health field, some of whom deny the value of a medical education and its uniqueness in the holistic approach to man's suffering. They would deny us experience with the stethoscope—a third ear, if you will, that allows us to hear the inner sounds of the human being. Or the ophthalmoscope, that has provided us with unique insights into the soul of man. Or empathic participation at numerous births, deaths, and sufferings of the flesh. All of these are not merely observational tools and experiential moments but are unconsciously incorporated into our very being; they form the image of the practicing psychiatrist. We must protect them from attack and dilution.

I firmly believe that we detract from our medical image when we adopt an alien vocabulary, a seemingly innocuous vocabulary but one that is inimical to our interests, as, for example, when we substitute "client" and "consumer" for the time-honored term "patient." There is nothing inappropriate in the term "patient," for its root derivation means to suffer, and who else indeed should be entitled to help in the health delivery system than sufferers? "Therapeutic contacts" become substitutes for doctor-patient relationships. The new jargon obviously emphasizes the business aspects of our profession, removes the human equation, leaves us open to the cruel accusation that we have become cold, calculating business people who have abandoned the time-honored aspects of humanism, of physicians who care.

The feeling that we are being reactive rather than proactive to issues and intimidating forces is pervasive in our Association. While we respond to situations and attempt to solve problems, I would like to see a long-range planning body established—a "think tank," if you will. In this way we can permit our best talent to formulate policy in a thoughtful, deliberative manner for years ahead rather than under the gun of an immediate crisis, although of course we will continue to act promptly in the light of past experience and in concert with our goals. I shall bend my efforts in the year ahead to bring such a body into being.

Robert W. Gibson, M.D.
One Hundred and Fifth President, 1976–1977

BY ROBERT S. GARBER, M.D.

"INDIVIDUALLY AND COLLECTIVELY we must demonstrate through responsible action that psychiatry is a profession worthy of the public trust." These words state in a nutshell the philosophy of the man who has just completed his term as one hundred and fifth President of the American Psychiatric Association. But such a philosophy did not emerge full-blown when he assumed the badge of office in May 1976. Roots of his responsible, public-spirited attitude were manifest early in Robert W. Gibson's life and were even more discernible as he moved into the leadership of one of the most prestigious psychiatric hospitals in the nation and took a major role in community and professional activities, meanwhile becoming a successful husband and father and a friend and colleague of a wide circle of movers and shakers.

Getting to where he is today involved the expected hereditary and environmental factors—and also perhaps a little magic. Robert Gibson's father, Walter Brown Gibson, was a reporter on the *Philadelphia Ledger* and a free-lance writer of books on mystery, magic, and the occult. In 1931 he would turn out a mystery story whose hero was a debonair man-about-town given to solving heinous crimes in his spare time. "The Shadow" became one of the most popular series of magazine stories ever published and the basis of the enormously successful radio show many of us remember from our younger days. An excellent amateur magician, Mr. Gibson was a confidant of Houdini, Raymond, Thurston, and Blackstone, and coached young Bob in the tricks of the trade. Growing up with Lamont Cranston for a sibling and famed prestidigitators for family friends has to have had an impact on the hero of this tale.

Dr. Garber, a former APA President, is President and Chief Executive Officer, the Carrier Clinic Foundation, Belle Mead, N.J. 08502.

Many people supplied material used in this biographical sketch. I acknowledge their help with thanks. I am especially grateful to Gwen, Mrs. Robert W. Gibson, and to the following: E. Carlton Abbott, Ph.D., Leo H. Bartemeier, M.D., Walter E. Barton, M.D., Francis J. Braceland, M.D., Dexter M. Bullard, Sr., M.D., Robert A. Cohen, M.D., Bliss Forbush, LL.D., Benjamin H. Kesert, M.D., R. Walter Locher, W. Berkeley Mann, John C. Ritchie III, M.D., Lewis L. Robbins, M.D., Melvin Sabshin, M.D., John C. Sonne, M.D., Robert E. Switzer, M.D., Perry C. Talkington, M.D., Mark M. Walter, Jr., M.D., and Michael Zales, M.D.

It is a pleasure to report that Walter Gibson has revived and updated Lamont Cranston to tell us what evil lurks in the hearts of men in these perilous seventies. How reassuring to know that both Bob Gibson and Lamont Cranston are on the job now!

Mrs. Walter Gibson, the former Charlotte Wagner, had interrupted her plans to become a professional singer in order to marry and raise a family. A fine swimmer, she gave her son Bob her love of both music and athletics. Bob remembers vividly the encouragement she gave him in his efforts to excel at sports and the many hours she invested in transporting the various teams he joined to competitions. She also urged him on in his studies and was a strong backer of his hopes to be a physician. Still a major force in the Gibson story, she has recently emerged from a bout of bad health and is reported to be once more in fine fettle.

Bob's magical background comes through in the comments of the many people whose lives touched his in those growing-up years. The charisma was evident early on. One cohort cited another radio hero of those days, Jack Armstrong. "Right from the first, he was the all-American boy, making straight As, charming his contemporaries and elders, and excelling in football, wrestling and track." Being a guard, as he was in those days of one-platoon single-wing play, could have helped him acquire the strength he has shown in his career—every other play went over the guard in those days. Recognition came early: he was president of his high school class and of the student council and made the Pennsylvania State wrestling finals. A younger stepbrother recalls, "He was bigger than I was and could beat the tar out of me. But I respected Bob because he took the time to help me to be an athlete good enough to play with him and his friends."

His mother described him as a boy who never wasted any time. "He was a driver and spent his time on his books, reaching out in many lines as if seeking to find out what would interest him most."

The superintendent of his high school remembers clearly an incident when Bob was asked by a teacher why he had elected to take five major subjects instead of the required four. He answered, "Well, it's there and I might as well take advantage of it." That was one of the considerations that led the principal to declare

Bob Gibson one of the ten best students who ever graduated from Lansdowne High School. Bob was ahead of the recent surge of students interested in filmmaking, having become an accomplished filmmaker in the forties. He did the shooting, editing, and splicing of his own action films, the most adventurous of which was shot from the front seat of a toboggan racing down a slide at Lake Placid. His interest in filmmaking may have been cooled somewhat when he tried to shoot an oncoming snowball and got it full in the face.

COLLEGE AND MEDICAL SCHOOL

Bob went to Lafayette, serving as president of the freshman class and becoming Middle Atlantic States light heavyweight wrestling champion. The accelerated Navy V-12 course moved him on to Swarthmore and to service as a corpsman at the Philadelphia Naval Hospital. The young man showed his considerable ingenuity and organizational ability when he promoted a back-rubbing contest among the nurses. He and another corpsman served as judges of the various contestants' skills; the only way they could do that was to themselves become the "rubbees."

Girl-gathering activities stopped soon afterwards, when Bob gathered in a wife, marrying Gwendolyn Locke after his first year of medical school. Only one other of Bob's school classmates was destined to become a physician, and he was Bob's best friend, Gwen's date prior to Bob, and the one who introduced the future Dr. and Mrs. Gibson. After the introduction Bob made his interest in Gwen known to his friend and the competition was on. Bob notes that both men became psychiatrists and that it was Gwen's influence that was behind this. Gwen claims to have wondered for years whether that was a compliment or an insult!

When Bob and Gwen arrived at the University of Pennsylvania Medical School, married students were still exceedingly rare birds. He was the first married man to be president of Alpha Kappa Kappa, and he and Gwen were in great demand as chaperones for fraternity parties; the rules stated only that chaperones must be married couples, not that they had to be old folks. One wonders how inclined the young newlyweds were to break up the couples who retreated to dark corners of the fraternity house.

Bob's skills as magician and craftsman are remembered by his Penn classmates. Card-playing cronies often wondered if legerdemain was a factor in his extraordinary winning streaks, but one of his often beaten friends thinks it was just skill. He recalls that Bob could replay bridge hands days later, remembering each card and the exact order of the play.

Gibson resourcefulness benefited both the fraternity and the Gibsons when Bob and his stepbrother took on the job of remodeling the fraternity house kitchen. Neither of them knew one end of a hammer from the other, but the fraternity was tight on funds and so were the Gibsons. Operating at night so the building inspectors wouldn't get wind of the amateurs at work, the brothers did the job in exchange for free board. Bob and Gwen recall eating free at the house for two and a half years, since no one was quite sure when the debt was finally paid.

ENTRY INTO PSYCHIATRY

Because of his accelerated program Bob graduated three months ahead of the time his internship was to begin and spent that time on the staff of Trenton State Hospital. The writer, then assistant director at Trenton, had made him an offer he couldn't refuse: $250 a month, a furnished apartment, and a job for Gwen. It was a fateful time for the profession and a memorable period for the writer, who watched Bob's growing involvement in the plight of the psychiatric patient.

A former classmate recalls his own years on a biochemistry fellowship when he talked with Bob, by then doing his residency, about their plans for the future. "I remember Bob talking then about how people were basically good, but that their goodness had often been blocked from developing because of events which had made them into hostile or mixed-up people." Colleagues in his later career confirm that he has maintained that basic faith in the goodness of human nature. We can be pleased that this view of humankind rather than The Shadow's sinister opinion prevailed in his thinking.

While he was on duty at the Bethesda Naval Hospital, Bob was recruited for residency at Chestnut Lodge. The recruiter was then tapped himself for the National Institute of Mental Health. "I told myself that I should be pleased that I'd been a benefactor for Dexter Bullard even though I didn't get to work with Bob at Chestnut Lodge. We have collaborated over the years in a variety of other situations. He is a truly outstanding person and I've taken great pleasure in watching his steady growth to this present position of leadership and recognition."

CHESTNUT LODGE

The busy resident somehow managed to find time to write books and lyrics for the annual staff musicals at Chestnut Lodge, and his interest in music continues to this day.

A memorable patient of the Chestnut Lodge years was Miss H.L., a remarkably docile and untroublesome patient except for one unfortunate habit: she was given to stuffing towels into the toilets and flushing them. The results were major plumbing crises that necessitated digging up pipes all over the grounds to remove the blockages. It must have been something of a relief when she was transferred to Sheppard and Enoch Pratt Hospital. Years later, when Bob was directing major reconstruction of the aging Sheppard and Enoch Pratt plant and the grounds looked like a

World War I battlefield, the medical director of Chestnut Lodge paid a visit. Looking over the trenches, craters, and piles of rubble that disfigured the grounds, he commented, "I see you still have Miss H.L. with you."

During his time at Chestnut Lodge, Bob worked on an intensive patient study which was the basis for *Schizophrenia and the Need-Fear Dilemma*, a book of which he was a co-author. The work is a major contribution to our understanding of the psychological aspects of the illness in a time when advances in our knowledge of the biological problems involved tend to be getting most of our attention. Taking the broad view is characteristic of Bob Gibson.

SHEPPARD AND ENOCH PRATT

In 1960 Bob became director of clinical services at Sheppard and Enoch Pratt Hospital. Three years later, as the fourth medical director, he assumed responsibility for the complete administration of this private psychiatric hospital. (Two of his predecessors, Edward N. Brush, M.D., and Ross McC. Chapman, M.D., had served as Presidents of APA.) It was a critical time in the history of the institution, which had served the mentally ill for more than 70 years. To many medical people, the day of the private psychiatric hospital was over. "The Sheppard," once a country hospital eight miles from Baltimore, was being engulfed by Baltimore's spreading suburbs and by the rapidly growing town of Towson. There was a strong feeling that the hospital should sell off most of its 400 acres of now valuable land to housing developers and build a small hospital in one corner of the remaining property. The real estate sale would endow such a small hospital comfortably for years to come. However, the new medical director convinced the trustees to advance rather than retreat. The Gibson dream was of an expanded institution offering the best of inpatient care, research, community service, and the training of mental health professionals.

The original structures, dating from 1853, underwent major remodeling (1). New programs and procedures were initiated, and the hospital was on the march. Land was sold to the Greater Baltimore Medical Center, St. Joseph's General Hospital, and Towson State College. Gibson was responsible for the establishment of a committee that supervised the cooperative efforts of these institutions with Sheppard Pratt, all working on common problems and on programs of mutual support. The hospital provided psychiatric educational programs to the Greater Baltimore Medical Center and received aid from the center in maintaining the Sheppard Pratt crisis clinic. St. Joseph's helped in various community mental health programs and in the provision of prompt medical care. Sheppard Pratt provided psychiatric assistance to the students and faculty of Towson State College and clinical experience to Towson psychology students. A joint Towson-Sheppard training program for mental health workers now leads to a Bachelor of Science degree and to certification as a mental health technician.

The Gibson approach stressed the traditional role of the treatment hospital, providing psychotherapy based on the life experiences of the patients and on their need to integrate themselves into their communities. A team approach was initiated, and the numbers of psychiatric residents, social workers, and occupational therapists increased. Training for psychiatric nurses was carried out in cooperation with nearby community colleges.

Although himself a fully trained psychoanalyst, serving as training and supervising analyst of the Washington Psychoanalytic Institute, Bob has been open to all valid developments in psychiatry. Sheppard Pratt uses a wide variety of treatment modalities in treating both adult and juvenile patients.

The number of patients admitted doubled, as did the number of physicians in training. The burgeoning staff of social workers more than doubled their services to neighboring hospitals, colleges, and the community-at-large. New programs have also involved the hospital with correctional schools, clinics, police training schools, and community mental health centers.

The number of long-term patients steadily decreased, replaced by adolescents and children coming for treatment. Bob led the child guidance program in its expansion to a five-day service for children 5 to 12 years old who were too disturbed to attend school. An inpatient service was initiated for the same age group; the program took over part of a building that had once been filled with long-term adult patients. A high school and a junior high, which share the structure, have been accredited by the Maryland Department of Education.

Another structure, once used to house nursing students from distant areas, became available when the nursing trainees began coming from local colleges and so could commute from their homes. Again walls came down, pipes went in, and wiring was overhauled as another building was reshaped to accommodate more of the director's new programs. For several years it looked as if not Dr. Gibson but Miss H.L. was the busiest person at Sheppard Pratt!

His reorganization of Sheppard Pratt had much to do with his receiving the Edward A. Strecker Award, given by the Institute of the Pennsylvania Hospital each year to "a young psychiatrist who has contributed the most in the field of psychiatry." That also seems an appropriate description of the man whose progressive ideas, organizational ability, and strength of purpose were instrumental in Sheppard Pratt's receiving the APA Hospital and Community Psychiatry Gold Achievement Award in 1972 "for demonstrating that a private hospital can modify its traditional role and become a catalyst in the development of community services."

We come back to speculating about his early contact with magic and the mysterious: those who have worked with Bob Gibson at Sheppard Pratt wonder

out loud how it is that so many of his prophecies about things to come have materialized in exactly the ways he has predicted. The vice-president of the Sheppard and Enoch Pratt board of trustees describes Bob as a person who can keep more balls in the air and drop fewer than anyone he has ever encountered.

COMMUNITY AND PROFESSIONAL ACTIVITIES

Witness his involvements in the community and the profession that he manages to sustain in addition to his work at Sheppard Pratt. He was the first chairman of the APA Commission on Standards of Practice and Third Party Payment, was chairman of the Advisory Council to the Maryland Comprehensive Health Planning Agency, a consultant to the Maryland Medical Assistance Program, treasurer of the Maryland Health Maintenance Committee, and was recently appointed to the newly formed State Health Coordinating Council. He has been a frequent spokesman before committees of the U.S. Senate and House of Representatives, and the only psychiatrist to be made a Fellow of the Association of Mental Health Administrators. Somehow he has also managed to do clinical research; for example, he was principal investigator for an Office of Naval Research Project comparing the family background and early life experiences of manic-depressive and schizophrenic patients. He also was editor of the book marking Sheppard and Enoch Pratt's 75th anniversary (2). Francis J. Braceland, M.D., wrote about this book:

> The diamond jubilee of a famous mental hospital is in itself a noteworthy event. When at the same time it brings together Ives Hendrick, Larry Kubie, Wagner, Brody, Eisenberg, Martin, Sarah Tower, Harold Searles, and a host of brilliant discussants, and allows them free rein to express their observations, it then becomes a not-to-be-forgotten occasion. *Crosscurrents* records that event and recalls its brilliance. (2)

Dr. Gibson served as president of the National Association of Private Psychiatric Hospitals and was a Trustee-at-Large and Secretary of the American Psychiatric Association before being chosen our President. In his introduction of Bob at the 1976 Institute on Hospital and Community Psychiatry, APA Medical Director Melvin Sabshin, M.D., commented: "It is noteworthy in this age of accountability that Dr. Gibson has been elected to national office in the APA by popular vote in five contested elections." As Secretary he was an active member of the Executive Committee. A fellow member of that 1972 committee recalls, "What stands out in my mind is his very even temperament, which seems to be consistent no matter how much confusion there may be around him or even possibly stress within him. He always maintains his objectivity and at the same time that he is serious he can add a light, humorous touch to break the tension. Thinking over the many years that I have known him, the phrase 'he wears well' comes to my mind. . . . I have never seen him act in a petty fashion, nor has he seemed to be motivated by his own needs for power or whatever propels him; instead he has always seemed to be focusing on the issues at hand and never seems to lose sight of them."

The Group for the Advancement of Psychiatry has also benefited from his service—as a committee member, and committee chairman, and now president-elect. As chairman of the Ginsberg Fellowship Committee, he was described by a fellow member as "one who showed us the value of teamwork and the art of having fun while learning. He also managed to provide direction while encouraging individuality."

The president emeritus of Sheppard and Enoch Pratt's board of trustees comments: "From twelve fruitful years of association I can say that Robert W. Gibson is a driver who puts his dreams and plans into reality by careful objective actions, winning hearty support from his associates and ever expanding his own experience and outlook. One by one, many of his dreams and goals have become realities, and the end is not in sight."

Many of his associates cite his ability to delegate responsibility as one of his finer talents; that may explain how he manages to keep so many balls in the air. Moving the imagery from theater to sports, we can say that once the ball has been handed off by Quarterback Gibson, the receiver can count on the play caller's insistence on knowing where the play is at all times and whether the play is advancing, being blocked, or pushed back.

And always there is the acknowledgment of the man's great good humor. In the midst of an endless debate at an APA Board of Trustees meeting, part of the committee took a rest-room break, which Bob welcomed with the comment, "At least in here people seem to know what they're doing."

He seems to have an inexhaustible repertoire of songs, which he is not reluctant to share with amiable assemblages. He also writes poems of the Ogden Nash school. And none who were there will ever forget the costume party of the National Association of Private Psychiatric Hospitals, when the only totally unguessable guest was an African witch doctor in full robe, feathers, magic wand, and animal tail. No one figured out who the masked dancer was until Bob took off the mask and accounted for the authenticity of his garb, which had been a gift to Moses Sheppard from a Liberian chieftain. Shades of The Shadow!

THE PRIVATE SIDE

There is also a private Bob Gibson, husband of Gwen and father of Robert, Jr., Christopher, and Peggy. Determined not to deprive his family of his attention no matter what the professional pressures, Bob has taken on a few more jobs to juggle, such as troop physician for his sons' Boy Scout troop and chairman

of their camping committee. When other fathers came up with elaborate excuses for not accompanying their sons camping, Bob threatened to recruit mothers. He took a ribbing about his attempt to spend weekends in the woods with the women and his supposed disappointment when the other fathers were shamed into showing up. Bob and Gwen have produced three winners in Robert, Jr., a Baltimore probation officer working on his master's degree in psychology; Christopher, on duty with the Navy in Pearl Harbor; and Peggy, a Western Maryland freshman planning to be a physical therapist whose healing talents are now lavished on her thriving plants and Polish rabbits.

Gwen sees herself as one of those women raised to perform well in one sort of role, then moved by changes in the script to learn a whole new part. She has maintained her early commitment to being an effective wife, mother, and homemaker as she has worked out her own professional goals. She has become quite a juggler herself, keeping all the home front balls in the air while tossing in a B.A. from Towson College, a master's degree from Johns Hopkins, a job at the Baltimore City Psychiatric Day Care Center, activities for the Maryland Art Therapy Association, and the tasks of treasurer and program chairman of the American Art Therapy Association. No one who knows the Gibsons is without praise for the way Gwen has played helpmeet in Bob's professional and personal life—mother of a fine family and newborn professional in the changing "outside world."

Gwen's comments about Bob make him seem almost without flaw. Almost. He does have a failing, she reports. He goes into culture shock when they travel. When a Peruvian asked him in Spanish for directions to some point in Lima, he stammered, "I don't speak English." And when a passerby did the same in England, Bob replied in a British accent.

Despite this wife's eye view of Gibson the Traveler, an eminent Past President of this organization describes Bob in this way: "He looks like, acts like, talks like, and *is* the kind of a guy that you would like to have represent psychiatry anywhere." He has done just that as President of the American Psychiatric Association for 1976–1977. Your author stands overwhelmed by the catalogue of admiring adjectives he has accumulated in the interviews for this article: "serious, thoughtful, logical, decisive, articulate, clear-thinking, compassionate, considerate, professional, trust-evoking, strong-willed, flexible, amiable"; and from his mother: "driving and insatiably curious." The writer can only say in summation that it is an honor to have worked with Bob Gibson over the years and to have had him as our President this year. To quote Virgil in his description of a hero of his times, "*Quantum instar ipso est*": None but himself can be his parallel.

Psychiatric Eclecticism: A Cognitive View

BY JOEL YAGER, M.D.

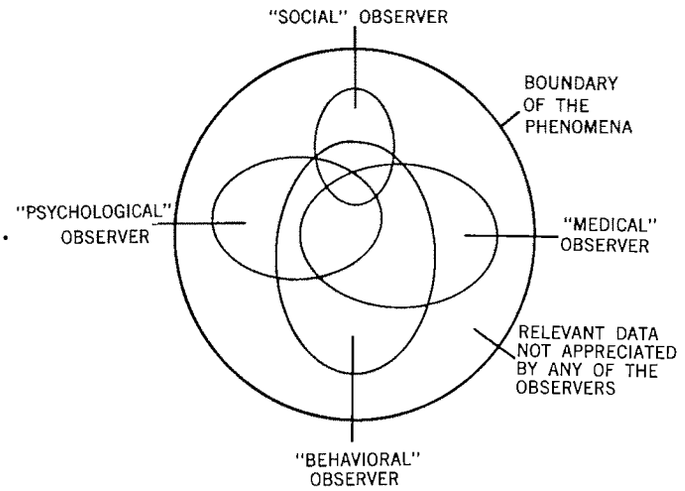
Pluralism is necessary in psychiatry to compensate for the errors and biases characteristic of the equipment we use to appraise clinical "reality"—our own perceptual-cognitive apparatus. Our attention to clinical situations is skewed: we notice "data" consistent with past assumptions and formulations, and consequently, those views are reinforced by our perceptions. The eclectic posture involves approaching each clinical situation from multiple theoretical perspectives and settling on a perspective that most closely agrees with the patient's needs and wishes without sacrificing the best information available to the psychiatrist. Such eclecticism defines the psychiatrist's role as that of a broad-based scholar who can apply what he knows to the clinical situation. The author discusses the implications for clinical practice and psychiatric education.

"ECLECTICISM" IN psychiatry has become fashionable in some circles and the subject for concern in others. The term itself has assumed different meanings in different contexts (1–3). It has been variously regarded as a psychiatric ideology consisting of more than just psychoanalytic psychiatry, an ideological interest in anything *except* psychoanalytic psychiatry, and an advocacy of an eclecticism of treatment procedures resting upon no identified single conceptual base. No existing theory adequately explains how all of the seemingly disparate practices employed in the service of "eclecticism" in the last sense might relate to one another. Simon (3) has pointed out the need for a useful theory of eclectic practice, "essentially a metatheory that would provide a rational basis for the application of other theories and types of practice." He concluded that general systems theory, which has been suggested as a theoretical basis for eclecticism because of its attention to all levels of organization from the molecular to the molar, has several limitations that render it inadequate to serve as such a theory.

Dr. Yager is Associate Professor of Psychiatry and Director of Residency Education, UCLA Neuropsychiatric Institute and Brentwood Veterans Administration Hospital. Address reprint requests to Dr. Yager at the UCLA Neuropsychiatric Institute, 760 Westwood Plaza, Los Angeles, Calif. 90024.

Drs. George Saslow, Ransom Arthur, Manuel Straker, Marvin Karno, and Steven Marmer provided helpful comments on previous drafts of this paper.

In this paper I propose that eclecticism can be profitably viewed from a different vantage point. My major thesis is this: eclecticism is made necessary not because of how "reality" is organized (the argument made from general systems theory), but rather because of how *we* organize reality; in other words, eclecticism is made necessary by the properties of our own perceptual-cognitive apparatus.



FRAMES OF REFERENCE AND THEORETICAL ORIENTATIONS

Lazare (4) has dramatically depicted the major problem facing the psychiatric clinician; i.e., human behavior is so complex that any one perspective is insufficient for a full appreciation of all there is to see. To illustrate, he presented a hypothetical case report and showed how observers oriented to the medical, psychological, behavioral, and social systems each focused on somewhat different data, appreciated a different reality, and drew different conclusions about etiology and implications for therapy. Yet the different perspectives are not necessarily mutually exclusive; in fact, they may complement each other in important ways. The clinical perspectives interact with the clinical situation as represented in the Venn diagram in figure 1 (taking into account that even the most thorough assessment may fail to recognize or elicit pertinent information).

The theoretical perspective performs two functions for the clinician: it organizes inquiry, observations, and understanding and simultaneously limits the field of vision. Both are necessary. Without a schema for searching, examining, and appreciating data, the clinician would be bewildered by incomprehensible chaos. Yet the same schema does the clinician the disservice of serving as a filter that, while selectively sharpening his focus on some areas, selectively excludes others.

Frank (5) has referred to the "assumptive world," the filters through which experience is processed and our conceptions of "reality" emerge. We psychiatrists, too, process "reality" through our own preconceptions to see things that fit with our usual ways of appreciating human behavior and pathology. Moreover, many of our "basic data" are themselves impossible to separate from context; what may appear as depressed mood in the context of an affective disorder may take the form of blunted affect in the context of schizophrenia.

FIGURE 1
Clinical Data Processed by Four Observers with Different Theoretical Orientations

Before we can know how reality is organized we need to examine the equipment used to measure "reality" and to learn its limitations and biases.

PERCEPTION

Psychiatrists who share common concepts frequently disagree about the presence of key clinical phenomena in specific situations. Seitz (6) found that senior analysts experience great difficulty in their attempts to agree upon the interpretation of the same material, "perhaps because various observers focus on different parts of the total picture." Other studies using analytic data, such as the work by Luborsky and associates (7), confirm the difficulty of reliable observation. Studies of nonpsychoanalytic psychiatric observation offer similar conclusions.

Cross-cultural studies reveal such differences in perception (8). Not only do American and British psychiatrists viewing filmed interviews diagnose patients differently, but they also selectively see different symptoms, usually those consistent with the diagnosis chosen. In general, American psychiatrists report a greater number of symptoms than do their British counterparts.

While clinicians using symptom-rating forms may agree about the interpretation of observable behavior (9), substantial difficulties remain. Even within the same institution, and given the same patient interview, clinicians sometimes disagree about phenomenological evidence of such conditions as delusions, thought disorder, and impairment of object relations (8, 10–13). Kendell (12) found that registrars' opinions about the relationship between "psychotic" and "neurotic" depression biased their ratings of depressed patients in spite of the fact that they used a standardized 41-item scale that required both historical and phenomenological information. For similar reasons, senior analysts' ratings may be even less reliable than those of house staff. Little (14) referred to this common phenomenon as "concept driven perception" and noted that it is not limited to the field of psychiatry. "Conspicuous interobserver disagreements have been demonstrated in the interpretation of x-rays, in endoscopy, in cardiac auscultation and in such an apparently straightforward observation as clubbing of the fingers" (14).

INFORMATION-PROCESSING CHARACTERISTICS OF THE PARTICIPANT-OBSERVER

As diagnosticians we use information that we are scarcely aware of, and we prefer to see and interview patients ourselves rather than trust the impressions and evaluations of others. Psychiatrists frequently form quick diagnostic impressions of patients—in two studies (13, 15), as early as 30 seconds to 2–3 minutes after the beginning of a filmed interview. Again, this phenomenon is not limited to psychiatry: neurological residents' tentative hypotheses are formed almost before the interview begins (16), and the same holds true for experienced internists (17). While many of the diagnoses made within the first 3 minutes of an interview involve "obvious cases," with good agreement between raters, with many others there is a major disagreement between raters.

We seem to operate as "pattern recognizers," checking our perceptions against our cognitive schemata for confirmation or refutation. We construct internal models of reality and shape our perceptions to agree with those models (18). Such internal models may allow us to recognize external events on the basis of a few "key" features and to extract signal from noise. However, the disadvantages of this internal model system—which may more or less accurately describe our perceptual-cognitive "equipment"—are several: no model is entirely accurate, and a system may be misled by its model; further, internal model systems are conservative and may be slow to change even when change might be most adaptive.

We appear to construct cognitive schemata by filling in the dots between scattered bits of evidence, using a sequence of our own design or a design borrowed from our friends and authorities. It is only when we can perceive a reality full of redundancies, where many bits of evidence converge in supporting our concepts, that we may begin to appreciate a relatively illusion-free reality (18).

COGNITIVE FACTORS IN THE CHOICE OF THEORETICAL ORIENTATION

We currently know little about the influences that determine why a given individual will select a specific theoretical orientation. A tendency toward ideological polarity is widespread throughout a variety of in-

tellectual domains, including mathematics, metaphysics, art, politics, and education, to name but a few (19).

Studies of psychiatrists' perceptions and thoughts reveal that factors which influence the perception of data and the diagnoses selected and adhered to include the views of senior, prestigious team members (10), the order in which information is presented to the examiner (13), the age of the psychiatrist (8), and the predominant modes of psychiatric thought to which he has been exposed. Personality differences are also important, and they may partly determine differences in the "style" of arriving at diagnoses (20), as well as the directions in which we each characteristically and systematically distort data (10, 21). Some research (22) suggests that clinical judgments are influenced by attitudinal variables within the therapist, such as tolerance, humaneness, and permissiveness, or, in contrast, disciplinarian, moralistic, and harsh qualities.

While the way in which psychiatrists think about clinical problems, and perhaps their theoretical orientations as well, may to some extent be related to differences in cognitive style, there has been little study of such possible relationships. The concept of "cognitive style" refers to several distinct qualities of thinking, such as modes of information handling (23); the rigidity, differentiation (24), and complexity of thought (25); the tendency to augment versus reduce the impact of incoming stimuli (26); and the degree of field independence versus field dependence (27). Field independent perception is the tendency to experience parts of a field as discrete from the organized background, while field-dependent perception is dominated by the overall organization of the field, with the parts perceived as fused. Field independence has been interpreted as indicating more psychologically differentiated and analytic thinking than field dependence. (Both styles are important, however, and a flexible combination of the two may be most adaptive.)

Two studies (28, 29) have examined the relationship between field independence/dependence and the characteristics of type A and B therapists, as originally described by Whitehorn and Betz (30). Both studies demonstrated a relationship between type B qualities and field independence. (Type B therapists were originally found to have vocational interests similar to those of printers and mathematics or physical science teachers, as measured by the Strong Vocational Inventory, while type A therapists' interests resembled those of lawyers. Type A psychotherapists were thought to be more effective with schizophrenic patients [30].) Although many questions remain about the type A-B therapist differentiation (31), and no conclusions can be drawn from these reports about cognitive styles and theoretical orientations, such research illustrates the potential for this approach in future studies. For example, it would be of interest to know whether field independence/dependence is correlated with a tendency toward atomistic versus holistic ways of viewing human behavior.

POLYFOCAL REALITY AND PSYCHIATRIC THINKING

Reliable and valid observations do exist in the field of psychiatry, but the empirical base upon which we operate is as yet meager. Moreover, in psychiatry it is not the individual "pure facts" that are exciting or useful. These facts, processed through our requirements for methodological purity and taken individually, are sterile, and they hardly fill our practical needs. Rather, it is the meaning that we assign to those facts and the theory that we use to order the independent "accurate" observations—the implications of these facts—that breathes life and generalizable clinical value into their existence. As a consequence, there are currently many ways of seeing reality—of connecting the dots. Each "complete system" actually does make a genuine contribution.

As a profession, how can we deal with this? Faced with a similar problem in comparative epistemology, the philosopher Steven Pepper (32) called for "post-rational eclecticism." In his evaluation of all the major theories of knowledge, he found each of the systems to be approximately of comparable adequacy to explain phenomena. Moreover, none is perfect, and each has its faults and limitations. (The systems that Pepper examined contain, loosely speaking, such theories as materialism, mechanism, pragmatism, platonic idealism, and "objective" idealism.) He concluded that each framework deserves attention in its own right and called for "rational clarity in theory and reasonable eclecticism in practice."

It seems that a similar state of affairs exists in the field of psychiatry and that for us, too, eclecticism is the most reasonable avenue.

THE PSYCHIATRIST'S TASK AND THE ECLECTIC OPERATION

Given that we can understand complex biopsychosocial phenomena from several perspectives simultaneously (at different levels of organization, and by focusing on different aspects of the same level), and given that at our current level of knowledge no one point of view in psychiatry is totally adequate, how can we conceptualize the psychiatrist's task? Broadly speaking, the psychiatrist's task is to effect the best possible solution for any clinical situation that presents itself, the strategy being decided upon only after many possibilities are considered.

Although this task definition seems deceptively simple, it clearly is not. The first step for the clinician in any situation is to decide what the problems *are* and where and how to intervene. How the problems are conceived, who defines them, the very words used in their definition—each of these elements helps shape the intervention. When confronted with a depressed person, if one thinks in terms of "primary affective disorder," "reaction to object loss," or "loss of posi-

tive reinforcers," the therapy chosen may follow from the words used in the original conceptualization. How, then, should one proceed?

The clinician performs what I term the "eclectic mental operation": he attempts to view a situation through each of several frames of reference—grids for the perception of "reality," if you will. These different perspectives are each applied to the specific situation, as if they were a series of different colored lenses and filters flashing one after another before the psychiatrist's eyes. The psychiatrist asks himself, "Concerning the psychodynamics of this situation, what should I be thinking about and asking? What about the biological aspects? What would a family therapist say? How do Szaszian and Laingian issues bear upon this situation? How would therapists of different orientations see the problem; what sorts of interventions would they recommend, and what sorts of results might they expect? What is the evidence for that?" The exercise is similar to what de Bono (33) has called "lateral thinking," i.e., approaching the available information from several points of entry and repatterning the information in an attempt to see alternative possibilities. Lazare (34) has suggested a number of hypotheses to be used by clinicians in initial evaluations.

The patient's perception of reality is another filter the psychiatrist must carefully consider. Patients' comprehension, assumptions, and expectations of their problems and of "appropriate" treatment frequently differ enormously from those of psychiatrists (35).

After viewing the situation from many vantage points, the psychiatrist can then define the problems for intervention and their relative priority. Aware that many truths can coexist, the eclectic psychiatrist will give primary attention to the "truths" that meet the following criteria:

1. Most closely coincide with the patient's definition of the problem, but not at the cost of setting aside the best judgment that the psychiatrist can make based on available information.

2. Most closely suggest a form of therapy that would be emotionally and philosophically consistent with the patient's beliefs and with his expectations of treatment. This is necessary because available evidence (36) suggests that the extent to which patients will return for subsequent visits, comply with medication prescriptions, and be satisfied with their care is related to how meaningful and acceptable the problem formulation and treatment are to them.

3. Based upon what the psychiatrist knows, offer the greatest promise for alleviating the defined problems as quickly as possible, while minimizing the potentially harmful biological, social, financial, and time-consuming side effects.

Within these "truths" there can be no such thing as a "bad" patient (although there can certainly be difficult and frustrating ones). The problem formulation and intervention mode most appropriate to each patient must be thought about and employed. Another implication is that treatment programs set up with too many preconceptions about what *all* patients require may frequently mismatch specific patients' needs.

THE PSYCHIATRIST'S ROLE: A DEFINITION BASED ON THE NEED FOR ECLECTICISM

If we take for granted certain essential qualities of the "good" psychiatrist, such as warmth, concern, intuitive awareness, sensitivity, and caution, the psychiatrist's role emerges as that of a broadly based scholar in the field of psychiatry and behavioral sciences who can apply this knowledge to clinical situations. Several features are implicit in this role definition, as follows.

1. There is a need for *broadly based* scholarship; one's knowledge cannot be restricted to one small theory or technique.

2. The psychiatrist needs to be a *scholar*—intimately familiar with current information in pertinent fields and aware of new developments. If he rejects one point of view in favor of another, the psychiatrist should be able to provide a critical, reasoned explanation, not one based simply on authority or subjective whim.

3. The psychiatrist needs a large repertoire of clinical skills and must be able to use these skills pragmatically.

4. When there is reason to believe that a patient would best be served by modes of therapy with which the psychiatrist is not familiar, he must be able to make appropriate referrals to other psychiatrists and to nonpsychiatric professionals.

While these pronouncements about the psychiatrist's task and role may seem utopian, they are offered as targets toward which professional development in psychiatry can move—directions only, since they can never be end points. Acceptance of this role definition carries with it implications for the objectives of residency programs (37) and for efforts in the continuing education of psychiatrists.

THE ASSESSMENT OF AN ECLECTIC APPROACH

When supporting a particular point of view in psychiatry, one is obligated to consider how that approach would measure up against others and whether it makes any difference to the patient. Bearing in mind the caveat that therapeutic approaches may be effective for reasons not at all related to their theoretical underpinnings, how could we study the relative value of an eclectic approach? Since eclecticism is not a specific treatment modality but a method for selecting the situationally optimal modalities from among all of those available in a given case, such a study would require attention not only to the outcome of treatment, in itself methodologically thorny, but to the process as well. "Doctor's choice" treatment situations might be com-

pared to specific treatments, where the reasoning that pertained to the doctor's choices was made explicit and could be examined for the degree to which eclectic reasoning (as described above) entered into the treatment plan. Experimental designs would, of necessity, be multifactorial, and such studies are difficult to do well.

With respect to the psychotherapies, for a wide variety of patients and problems there is as yet little compelling evidence that any one is incontestably superior to any other. Moreover, therapists with different orientations may have divergent opinions about the benefits of a particular therapy with a given patient (38).

In actual practice, the similarities between the various psychotherapies are considerable and the effect of these similarities may outweigh the differences. In addition, the very fact that a therapist *has* a system of therapeutic beliefs (that the patient may share) may itself be an important element in the effectiveness of the therapy by helping to evoke hope and combat demoralization in the patient (5). This situation creates the possibility of an increasing paradox: it is conceivable that a therapist who strongly believes in a narrow and perhaps scientifically unsupportable therapeutic system may be a *more effective* therapist for some patients than a therapist who is skeptical about that (or any other) method of psychological therapy. The process rather than the content may be the essential ingredient. In any event, for the approximately two-thirds of all patients who will derive some benefit from most types of psychotherapy, eclecticism may not make too much of a practical difference; at the least, any such differences may be especially difficult to demonstrate.

However, at least for some depressed (39) and schizophrenic (40) patients, recent studies have demonstrated the value of simultaneously employing a combination of treatment approaches (drug therapy together with some form of psychotherapy or environmental therapy) for achieving both symptom relief and improved social functioning. Each therapy is based on at least a different level of conceptualization, if not on categorically separate conceptions, about the pathogenesis of the patient's problems. Neither therapy is individually as effective as a combination of the two. Such rational applications of different therapies, each aimed at different aspects of a patient's problem matrix, are neither indiscriminate nor shotgun therapies. It is easy, and idealistic, to conceive of treatment programs that might combine elements of individual, family, and/or group methods, that employ elements of dynamic, behavioral, cognitive, social learning, Gestalt, drug, and/or a host of other therapies, with the treatment elements individually tailored after thoughtful appraisal of each facet of a patient's total situation. However, such eclectic treatment strategies have been criticized as being "shallow" and perhaps even counterproductive when compared with the use of only one form of therapy at a time, applied in depth.

Yet such objections do not fully appreciate the fact that empirical pragmatism—not theory-bound treatment—has been the cornerstone of advances in clinical medicine; useful theory not only grows from the insights it may provide, but it must build upon results. When facts about treatment effectiveness are few or conflicting, theory-based treatments may be clinically limiting, treating the theory and not the patient. A theoretical "shallowness" with an open-minded approach may be preferable to prematurely "deep" understanding.

Moreover, if the decision process outlined above is used to determine appropriate treatment for a patient, when the evidence indicates that one mode of treatment is best and that others used concurrently would add nothing or even detract from the value of the most effective treatment, then the best treatment should most certainly be used in pure form. Unfortunately, however, with regard to the psychotherapies there is reason to suspect that even with orthodox adherents to a theoretical model for treatment, their actual practices vary enough from one another and from the model that pure forms of such treatments may be difficult to identify.

It may be that the benefits of eclecticism can best be demonstrated through a review of the management of "difficult cases," i.e., those not responding to an initial treatment strategy. The psychiatrist's ability to rethink the problem, to "shift conceptual gears" and find new points of approach, should theoretically increase the likelihood of effective outcome. However, if the psychiatrist lacks either the cognitive flexibility to shift perspective or sufficient knowledge about alternative frames of reference or alternative treatment skills, a patient may either continue to be unnecessarily treated by an inappropriate method or may be prematurely consigned to the "treatment failure" category.

THE LIMITS OF ECLECTICISM

At best, an eclectic approach can hope to offer patients the most reasonable treatment approach for their particular problems at a particular time in psychiatry's history, but obviously there are no ready answers for many problems. However, professional education that encourages the learning of multiple frames of reference may temper the effects of the attention-skewing tendencies of our perceptual-cognitive apparatus.

In the last measure, our ability to be eclectic is limited by the skill with which we select from and the extent to which we keep up with and integrate the painfully overwhelming mass of existing and yet to be created biopsychosocial information that provides skeleton and flesh to the various frames of reference. At the same time, we are all to some extent bound by our habitual sets and attitudes, perhaps some more than others by virtue of differences in cognitive style. Since these factors may intimately affect the quality of

care that our patients receive, they deserve careful attention and further study.

Auditory Evoked Potentials and Selective Attention in Formerly Hyperactive Adolescent Boys

BY ANDREW J. ZAMBELLI, PH.D., JOHN S. STAMM, PH.D., STEVEN MAITINSKY, M.D., AND DAVID L. LOISELLE

Although many of the prominent symptoms of minimal brain dysfunction (MBD) subside during pubescence, adolescents who had MBD during childhood may have persistent neuropsychological dysfunctions. The authors studied the auditory average cortical evoked potentials and behavioral responses of 9 formerly hyperactive adolescent boys and 9 matched control subjects who performed a selective attention task. Experimental subjects showed indications of impairment on both electrophysiological and behavioral measures of selective attention. Although the findings are consistent with a neurodevelopmental lag interpretation of MBD, they may also imply a persistent dysfunction related to the frontal association cortex.

THE TERM minimal brain dysfunction (MBD) refers to a constellation of behavioral and physiological aberrations during childhood that include soft neurological signs, hyperactivity, and attentional deficits (1). The diversity of symptoms involved in the MBD diagnosis has led to the view that this disorder may not represent a unified syndrome, but rather may include a number of separate etiological categories. In spite of the heterogeneity of the MBD symptoms and the lack of a unified etiology, the large amount of data presently being gathered on children diagnosed as having MBD provides useful characterizations of the psychological and physiological variables associated with particular symptoms, thus allowing for effective treatment and possible clarification of etiological factors.

There remains, however, a great deal of uncertainty with regard to the prognosis of the child with MBD. The concept of the disorder as a manifestation of neurodevelopmental lag during the childhood years has led to the inference that MBD consists of transitory dysfunctions that will be overcome with continued maturation. This concept is derived largely from findings that the diagnosis of MBD is often based on criteria that are abnormal only in terms of the child's age (2). These criteria include clinical and behavioral signs from neurological and electrophysiological evaluations, as well as psychological measures of attention, cognition, and impulse control. Further support is obtained from the observation that many of the presenting symptoms, particularly hyperactivity and attentional deficits, appear to subside at the beginning of adolescence (3, 4).

An increasing number of studies, however, report persisting neuropsychological dysfunctions in adolescents and young adults who had been diagnosed as having MBD (5–7). In a five-year follow-up study with 6- to 13-year-old boys, Weiss and associates (6) found substantial evidence for attentive and cognitive dysfunctions, restless and impulsive behavior, and poor social adjustment and academic failure. These findings support the view that MBD is a manifestation of a persistent, if not permanent, disorder (8).

A definitive picture of the fate of the MBD child is difficult to obtain. Research into any aspect of the syndrome must contend with the heterogeneity inherent in the classification of MBD. Several investigators have adopted research approaches aimed at reducing this heterogeneity by statistical methods (9) or by classification of subgroups (10, 11). In a systematic investigation by Douglas (10), a group of hyperactive boys was selected from a larger clinical population according to multiple medical, psychological, and behavioral criteria. We followed this approach to select for study a group of boys with hyperactivity and/or attentional deficits as major presenting symptoms.

The aim of the present investigation was to measure a number of neurological, electrophysiological, and behavioral variables in adolescent males who had been diagnosed in childhood as having MBD in order to: 1) assess the level of physiological and psychological functioning in this particular population compared to normal age-matched controls and 2) examine the adequacy of the neurodevelopmental lag concept in accounting for observations made during adolescence.

When this work was done Dr. Zambelli was a graduate student, Department of Psychology, State University of New York at Stony Brook, Stony Brook, N.Y. 11794, where Dr. Stamm is Professor of Psychology and Mr. Loiselle is a graduate student. Dr. Zambelli was also Visiting Fellow, Department of Physiology, College of Physicians and Surgeons, Columbia University, New York, N.Y.; Dr. Stamm is also Adjunct in Medicine, Nassau County Medical Center. Address reprint requests to Dr. Stamm.

The authors would like to thank Matthew Avitable and Richard Reeder for technical assistance and the pediatric residents of the Nassau County Child Development Center for their assistance in the administration of the neurological examination.

The investigation focuses on measures that have proved successful in discriminating between MBD and normal groups in childhood, including evoked potentials to sensory stimuli (12–15), evoked potential and behavioral measures of attention (9, 11, 16, 17), and soft neurological signs (18, 19).

One possible indicator of neuronal processes is the auditory averaged evoked potential. Satterfield and associates (12) reported that a group of MBD children had longer latencies and smaller amplitudes than normal age-matched controls for some of the late components of this response. These results were considered to support the neurodevelopmental lag concept, in view of Schenkenberg's (20) findings that normal subjects exhibited decreasing latencies and increasing amplitudes for these components during the age span of 5 to 15 years. Measurements of auditory evoked potentials, moreover, seem to be appropriate for investigations of MBD since they have been related to attentive functions, which are among the outstanding disorders in MBD children. Of particular use in investigating electrophysiological correlates of attention is the experimental paradigm developed by Hillyard and associates (21) for the measurement in normal adults of evoked potentials to task-relevant auditory stimuli. They found substantially larger amplitudes of a late component of responses to tone pips to which subjects were instructed to attend than to nonattended tones. In the present investigation we used this procedure as well as the presentation of standard auditory clicks in testing adolescent boys who had been diagnosed during childhood as having MBD.

METHOD

Subjects

The experimental group consisted of nine adolescent boys who had been referred several years previously for evaluation and therapy to the Child Development Center of the Nassau County Medical Center. The initial intake procedure involved extensive physical and neurological examination, psychological testing, educational evaluation, and any additional testing needed in individual cases. On the basis of the information thus obtained the clinic staff decided on a diagnosis of MBD.

In addition to the MBD diagnosis the presence of hyperactivity was also used as a criterion for inclusion in the study. A child was considered hyperactive on the basis of reports from teachers or school psychologists, interviews with parents, and the evaluation of the examining physician. Subjects were selected if reports from at least two of these sources indicated hyperactivity and/or attentional deficits. Records of boys selected for the study indicated that they met the following additional criteria when the initial diagnosis was made: 1) presence of soft neurological signs, 2) no major neurological disorders, 3) no sensory deficits, 4) IQ of 80 or above, 5) attending school, 6) academic deficiencies, and 7) subsequent treatment with amphetamine or methylphenidate. Quantitative data on response to drug therapy were not available but the clinical records indicated beneficial effects for the majority of boys. At the time of the experiment the boys had been off psychoactive medication for from 2 months to 4 years.

The median age of the group was 14.04 years, with a range of 12.9 to 16.13 years. Nine boys who attended regular school at appropriate grade levels and had no history of minimal brain dysfunction or learning disability served as a control group; their median age was 14.07 years.

After each subject was selected his parents were invited by letter to participate in the project. The nature of the experimental procedure and the possible benefits of the research were explained to them in conversation and in a written consent form.

Procedure

The subject was seated in a comfortable chair in an electrically shielded and sound-attenuated chamber. Hearing thresholds for each ear at the relevant experimental frequencies were obtained.

The recording session consisted of presentations of binaural sequences of clicks or tone pips through stereo earphones. A series of clicks (0.1 milliseconds duration, 63 db intensity) was delivered at a rate of 1 every 2 seconds for 2 minutes. The tone pips were used in a selective attention task similar to that described by Hillyard and associates (21). Independent random sequences of 800 Hz pips to the right ear and 1500 Hz pips to the left ear were presented concurrently; each pip was 68 db above threshold and 50 milliseconds in duration, with interstimulus intervals randomized between 450 and 1500 milliseconds. Each series consisted of 185 pips and lasted 3.25 minutes.

Approximately 10% of the pips to each ear were of a higher frequency than the standard pips—840 Hz (right ear) and 1560 Hz (left ear). The "signal pips" were randomly presented every 2 to 20 stimuli.

The pip sequences were recorded on audiotape and played to subjects 6 times during the experimental session. During the first 4 sequences the subject was instructed to attend either to the left or the right channel, count the number of signal pips, and report it to the experimenter at the end of the sequence; during the last 2 pip presentations the subjects were instructed to press a hand-held button each time a signal pip occurred on the attend channel. To reduce carry-over effects the transition between attending to each ear was separated by a presentation of the clicks, for which subjects were instructed to ignore both channels. Two counterbalanced sequences of attending to the left or right ear were given, with four or five boys in each group receiving each sequence. A 2-minute rest period was given between each auditory sequence.

The recording session was preceded by an instructional period in which subjects were informed of the

task and played a sample section of tape until the experimenter was assured that the subject comprehended the task and could make the required discrimination. Subjects were informed that if they responded with the correct number of signal pips they would be rewarded with fifty cents per sequence. Instructions were also given for reducing bodily and ocular movements. All subjects were cooperative and seemed to comprehend the instructions.

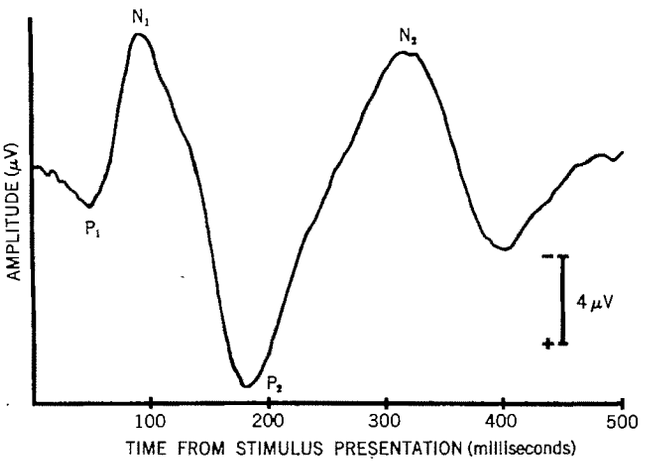
Electrocortical Recording

EEG electrodes (Beckman) were attached to the vertex (C_Z) of the scalp, the right mastoid (reference), and the forehead (ground). Nonpolarizable silver-silver chloride electrodes were placed above and within the outer canthus of the left eye. All electrode resistances were below 8K ohms. Recordings of vertex EEGs and eye movements were obtained via a polygraph (Beckman, Model-R) (bandpass filters .053 Hz and 32 Hz) and stored on analog tape.

Off-line averages of vertex evoked potentials (AEP) to the clicks and tone pips were obtained with a PDP-12 computer using a five-channel averaging program. Separate AEPs were obtained for each series of 360 tone pips to each ear under the attend-left and attend-right conditions and for 171 click presentations. Averages were for tone and click stimuli for 400-millisecond and 500-millisecond epochs following stimulus onset, respectively. Possible contamination of the AEP data by eye movement and eye blink artifacts was assessed via an editing procedure by which trials during which such movements were indicated by EOG recordings were deleted from computation of the AEP. Since the edited AEPs for the three subjects with the greatest number of such artifacts did not differ appreciably from the unedited AEPs, unedited averages were used for subsequent evaluations.

Behavioral Measures

The last 2 tone pip sequences, to which subjects responded by pressing a hand-held button, yielded behavioral measures of selective attention. Button-press data and response time latencies were recorded by the experimenter. A response was scored as correct if it occurred within 1.0 second after pip presentation.



After the experimental session each subject was given a neurological examination to assess soft neurological signs. The examiner was not informed whether the individual was an experimental or control subject. Each subject's parents were also asked to complete a 73-item symptom questionnaire (22).

RESULTS

Evoked Potentials to Clicks

The auditory AEPs had waveshapes similar to those reported by other investigators (see figure 1). To facilitate comparison with results of relevant previous studies (12, 13) the latencies and the peak-to-peak amplitudes of the late components, designated N_1, P_2, and N_2, were analyzed. Values for these components are indicated in table 1. There were no significant differences on any of the measures between the experimental and control groups (two-tailed Mann-Whitney U test, $p>.10$).

FIGURE 1
Representative Average Evoked Potential to 171 Click Presentations*

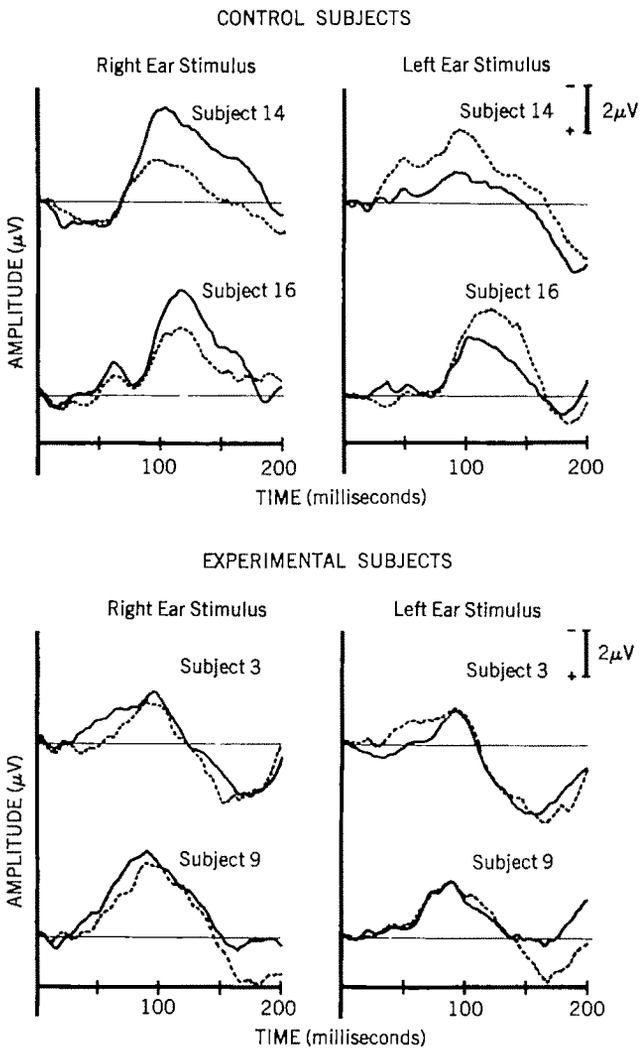
TABLE 1
Mean Latencies and Amplitudes of Averaged Evoked Potential Components for Experimental Group (N=9) and Control Group (N=9)



Component	Control Group	Experimental Group
Latency (milliseconds)		
N_1	88.5	86.1
P_2	170.3	176.8
N_2	318.6	315.9
Amplitude (μV)		
N_1–P_2	14.7	14.8
P_2–N_2	12.4	13.4

Evoked Potential to Tone Pips

Figure 2 presents representative AEPs to the tone pips for the attend and nonattend conditions from control and experimental subjects. The left and right columns are tracings from the left and right ear stimuli, respectively. The amplitudes of the N_1 peaks of the AEPs for control subjects during the attend condition were substantially greater than the N_1 peaks associated with the nonattend condition. This finding was consistent for tone pips to both ears. By contrast, the N_1 peaks of experimental subjects were not affected by the experimental conditions of attention.

The amplitudes of the N_1 and P_2 peaks of the AEP were measured baseline to peak, where baseline was considered to be the mean voltage over the initial 10 milliseconds of the AEP for each subject. Prior to statistical analysis the amplitude measurements for each

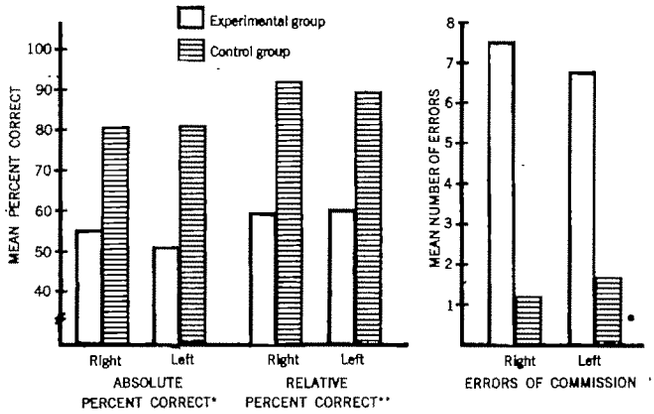
FIGURE 2
Representative Averaged Evoked Potentials Recorded from Vertex Electrodes in Two Experimental and Two Control Subjects*

*Averages are for 360 tone pips each to the right and left ears under conditions of attending to the right (solid lines) or left (dotted lines) signal tones.

subject for the attend and nonattend conditions were converted to a percentage of the attend condition to remove intersubject variability. In control subjects the mean of the N_1 amplitudes of the evoked potentials for the left ear stimuli was 26.0% smaller during the attend-right compared to the attend-left condition. For the right ear stimuli the mean of the N_1 component was 30.2% smaller during attend-left compared to the attend-right condition. Both of these differences were statistically significant by the Wilcoxen signed rank test ($p<.05$). For the experimental group, however, the corresponding differences in N_1 amplitudes were only 1.0% for the right ear and 12.8% for the left ear. Neither of these differences reached statistical significance (Wilcoxen test, $p>.05$). No significant differences in P_2 amplitudes between attend and nonattend conditions were found for either the experimental or control group. Thus the control group displayed a statistically significant electrophysiological sign (N_1 peak amplitude) of selective attention in both right and left ears; this sign was not observed in the experimental (MBD) group.

There were, however, considerable individual differences in N_1 amplitudes within each group. The average amplitude difference between the attend and nonattend conditions to the left and right ears ranged from 70% to −4% for control subjects and from 32% to −27% for experimental subjects. (Negative number indicates that nonattend amplitude was larger than attend amplitude.) The range for the experimental group reflected the fact that two of the nine experimental subjects responded with substantially higher N_1 amplitudes to the signal stimuli in the attend condition.

Behavioral Measures of Attention



The subjects' reports of the number of signal pips for each of the 4 presentations of the tone pip sequence were converted to scores of the difference between the number of pips that were presented and those that were reported. Error scores were substantially and significantly greater (Mann-Whitney U test, $p<.001$) for the experimental than for the control group. These total error scores, however, provided no information about errors of omission or commission in subjects' responses to individual stimuli.

More informative data with regard to subjects' attentive functions were obtained from the procedure of pressing on the button in response to the signal pip. The results for this procedure, presented in figure 3, indicated significantly lower correct response scores in the experimental than the control group (Mann-Whitney U test, $p<.01$). The deficiency of the experimental subjects was even more pronounced in terms of commission errors, i.e., button presses during periods when signal pips were not presented. The median scores for the two groups were 4 and 15, respectively, with ranges of 0 to 5 for the control and 3 to 21 for the experimental subjects. The two experimental subjects whose scores fell within the range of the control group were the same subjects who obtained substantially higher N_1 amplitudes under the attend than the nonattend condition. The button response scores were correlated significantly with the percentage changes in the N_1 component amplitudes, with rank-order coefficients of .41 for absolute correct, .43 for relative correct, and −.45 for commission error scores ($N=18$, $\alpha=.05$).

Neurological Examination

The findings from a 54-item neurological examination were evaluated in 10 categories found useful for the assessment of soft neurological signs (18). These included measures for dominance, right-left coordination, fine motor coordination, overflow movements, tactile discriminations, and global clumsiness. The total incidence of such signs was only 8 for the experimental and 5 for the control subjects; no significant group differences were found (Mann-Whitney U test,

FIGURE 3
Performance Scores of Experimental (N=9) and Control (N=9) Groups on Push-Button Response to Signal Pips to the Right and Left Ears

**Relative percent correct=ratio of correct responses to sum of correct and incorrect responses.

$p>.10$). The 8 signs among the experimental subjects was a significant decrease from the 21 soft neurological signs that had been indicated in their childhood records. A decrease in soft signs was found for every experimental subject.

The data obtained from the 73-item symptom questionnaire completed by subjects' parents were grouped into 24 categories for analysis. Results indicated a low incidence of symptoms for all subjects; experimental subjects showed a significantly higher incidence than control subjects on only 1 item, restlessness (Mann-Whitney U test, $p<.05$).

DISCUSSION

The data offer a number of insights into the adolescent fate of the child with MBD. The boys studied present behavioral and neurological pictures free of some of the traditional symptoms present in MBD children. Furthermore, the measures of the evoked response to auditory clicks appear in contrast to the reports of differences in amplitudes and latencies observed in young MBD children (8 years median age) compared to age-matched controls (12, 13). Our findings are in general agreement with the maturational lag view of the MBD syndrome and are consistent with the improvement in symptoms that can be inferred from the clinical records of the experimental subjects.

However, the electrophysiological and behavioral measures on the selective attention task point to important continuing deficits in the experimental subjects. The substantially higher error scores by these boys are in agreement with the persistence of attentional deficits that has been found in follow-up studies of hyperactive children during early adolescence (6, 11).

The electrophysiological measures for selective attention, when interpreted in light of the findings by Picton, Hillyard, and associates (23, 24), offer an insight into the possible neuronal system involved in the deficiency. In a detailed study of averaged auditory evoked potentials recorded from multiple scalp locations, these investigators found that the maximum amplitudes for the late components (P_1, N_1, P_2, N_2) were observed over the frontal and central regions and inferred that this represented widespread activation of frontal cortical neurons. In assessing the effects of attentive functions on AEP components, Picton and Hillyard (23) found no significant changes in components earlier than N_1 and concluded that processes of human auditory attention are mediated by a central mechanism involving changes in responsiveness in the frontal association cortex.

The findings by these investigators are in agreement with the results from our control subjects of increased N_1 amplitudes concomitant with tasks requiring more difficult selective attention. Our finding of the lack of this relationship in experimental subjects may imply persistent dysfunctions related to the frontal association cortex, thus providing additional support of the concept that frontal lobe disorders underlie the MBD syndrome (8). That the frontal lobes play a role in attentive functions has also been indicated by behavioral and electrophysiological findings obtained with brain-damaged animals and humans (25).

The interpretation of the present findings with regard to the concept of neurodevelopmental lag is complex, and several alternative hypotheses must be considered. The possibility that the persisting deficits in selective attention reflect permanent dysfunctions in the neuronal systems that mediate this higher-order function cannot be dismissed. This interpretation would imply that, although some of the dysfunctions subside during the maturational process, others, such as attentional disorders, persist throughout the lives of many individuals who were diagnosed as having MBD in childhood. This possible outcome has been obscured in previous clinical investigations because the diagnostic procedures used failed to push patients to the limits of higher-order functioning.

The present findings, however, may be explained in consonance with the neurodevelopmental lag hypothesis. Evidence has been reported in recent years indicating continuing development of cortical processes during the adolescent years. Thus normal developmental changes in measures of evoked potentials continue to age 17 years (20), and the amplitudes of the cortical contingent negative variation, a measure related to expectation of a meaningful stimulus, have been found to increase systematically between 6 and 15 years (26, 27). Since most of our subjects were in their early adolescent years, we cannot disregard the possibility that the behavioral and neurophysiological dysfunctions associated with the difficult selective attention task will be overcome with continuing maturation. This optimistic prognosis is supported by our

finding that two experimental boys, one of whom was the oldest in the group, were indistinguishable from the control population on every measure in the experiment, including those of selective attention. In view of their profound dysfunction in childhood and their unremarkable adolescence, one is compelled to consider maturational lag as an important underlying process in MBD.

These two interpretations of the findings are not necessarily mutually exclusive, nor are they the only ones with validity. In consideration of the unknown etiology of MBD and the considerable heterogeneity of patients assigned this diagnosis (even in our study group, which was carefully selected according to multiple criteria), it is entirely possible that some children will overcome their disorders during adolescence, whereas others may remain permanently dysfunctional on higher order tasks. It is also possible that some children will retain behavioral handicaps developed in response to negative reactions from persons with whom they interact to the profound aberrations in their developmental history. Such secondary reactions may persist throughout the person's life, marring his or her abilities.

Although inferences with respect to the heterogeneous population of children diagnosed as MBD are limited by our small sample, insight may be gained into the relatively homogeneous subgroup in this study. This subgroup was chosen according to criteria similar to those used in other investigations (10, 12). Our findings support the increasingly accepted view (e.g., 28) that many children diagnosed as having MBD in childhood are not out of the woods with the cessation of most of their symptoms in early adolescence. Continued research is needed on homogeneous subgroups of the MBD population in order to delineate the behavioral and physiological characteristics of these individuals in their adolescent period.

Borderline Rage and the Therapist's Reponse

BY THEODORE NADELSON, M.D.

Borderline patients often engender feelings ranging from apathy to rage in therapists. The author views the borderline patient's rage as defensive against fear of total negation resulting from projective identification with hostile part objects. The therapist's withdrawal or anger parallels the patient's projection of affect. Countertransference offers the potential for understanding a patient's terror, but therapists may become fixed in identifications that distort their understanding. Clarity often comes slowly as the therapist directs attention to his/her own affective state in order to understand the patient's vulnerability.

THIS PAPER will focus on the therapist's response to the patient's aggression as the crucial issue in the long-term treatment of borderline conditions. With all borderline patients the therapist is always the object of projected bad or hostile introjects, which influence the relationship toward victim-victimizer reciprocity. The patient's anger suffuses the therapy, and the therapist must exercise considerable (and taxing) vigilance toward his personal reactions to this aggression. This vigilance has the potential to increase understanding of the patient's psychodynamics.

THE PATIENT'S AGGRESSION

Although there may be other more primitive or constitutional aspects of aggression in borderline character structure (1), I believe that an emphasis on the defensive function of the patient's hostility and on the manner in which the therapist receives, perceives, and reacts to it will provide a practical conceptual framework that may have operational value. My purpose is to offer a therapeutic alternative to apathy, withdrawal, or counterattack, which at times may seem natural, right, or "real."

Structural analysis (2–4) indicates that "highly specific defensive operations" underlie the aggressive behavior rather than the extreme aggressiveness, poor impulse control, or weak ego proposed by nonspecific approaches. It is often important to seek out the defensive aspect of the patient's aggression while reacting to attack; this mental operation helps to delay the therapist's response and may bring him closer to the essential issue of the patient's narcissistic vulnerability. Simply stated, the patient attacks in the interests of self-defense.

NARCISSISTIC VULNERABILITY

Early frustration by parental figures is probably an important developmental factor in borderline conditions. Patients feel they have been teased or toyed with with no regard for their emotions. Pent-up pregenital aggression tends to be projected onto parents, and early parental images are thus distorted in a paranoid way (1). In early parent-child interactions, parents may project their own needs onto their children excessively, never allowing them their individuality. Such feelings are also projected onto the therapist, who is seen as using the patient for his/her own ends. Often the therapist's response may support this conviction. As therapy proceeds, the projective distortion is corrected and the patient integrates or incorporates the therapist's concern for growth; this often leads to a focus on the individuation of the patient's own children.

My view of borderline and narcissistic patients emphasizes the narcissistic vulnerability that has arisen from their inability to integrate important early introjects, both bad and good (1). These patients have never arrived at a sense of self; they feel that they have "no right to a life" (5). The patient suffers from a continuing conviction that he/she is unwanted and unloved, unredeemable, damned, and guilty. This unsupportable feeling state must be dealt with continually, largely by splitting and projection of aggressive part objects. The threat that is posed to the borderline character derives from the negation imposed by aggressive introjects and from the defensive compromise itself, i.e., the splitting of the good from the hostile part objects. The splitting defense and the subsidiary defense of projection, however, prevent the borderline character from feeling whole; this also leads to a chronic sense of alienation in the interpersonal sphere. Such individuals are convinced that they can be eliminated or annihilated; one patient reflected that this would be done "casually or negligently." They feel they can be dispensed with like a used tissue.

The aggression that suffuses such patients' relation-

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Nadelson is Assistant Professor of Psychiatry, Harvard Medical School and Beth Israel Hospital, 330 Brookline Ave., Boston, Mass. 02115.

ships with others is also an energetic expression or assertion of self-preservation against fearful threat. In this context, aggression is defense rather than drive, as Rochlin (6) pointed out. Thus I am speaking of two conceptually separable components of this aggression. One involves splitting and subsidiary mechanisms and defense by projection of the bad internalized part objects onto others. The other component is the related assertion of self against a conviction of worthlessness and eroded self-esteem, continually presented to the ego by the hostile introjects. This second component of aggression, the one I am emphasizing, is an ego response to the constant pressure of threatened annihilation. The patient's continued struggle with ego diffusion (1) and shifting feeling states results from the presence of unassimilable part objects.[1]

Such patients often state that when they feel angry, they experience less vulnerability and more of a sense of being "alive," although such feelings are transient. Projection is defensive against an internal sense of negation; by projecting their lack of self-regard onto others, these patients achieve a temporary surcease from the constant claim made by their hostile introjects. Projected anger is a necessary accompaniment to their disowning their own self-hate and the threat the world imposes on them.

COUNTERTRANSFERENCE

It is as if all patients with borderline conditions engender a countertransference anger that represents the emergence of the aggressive part of the patient from within the therapist (4, 7–9). These are usual, natural responses of the reasonably well-integrated therapist to attack, control, and nullification (10). Also, the therapist's wish to help is frustrated and there is anger at not understanding and not being understood; these are specifically the therapist's difficulties. All therapists have a potential susceptibility to such responses to borderline patients, although some may be more repetitively susceptible (1, 11–15).

The pivotal issue in treatment (given that the therapist's needs are more or less stable) is the understanding of aggression as it emerges between the two principals in the therapeutic interaction. The therapist must be willing to realize the presence of intense and angry feelings that are often masked by a sense of unrest, fatigue, or disinterest in the patient. He/she may often wish to let the issue go, to get through the hour, because of fatigue or the thought that the patient is too refractory on that particular day. Such reactions are signals that the therapist is feeling worthless and helpless, i.e., is resonating with the patient's feeling state. It is often necessary at such times for the therapist to examine his/her own feelings silently and to see how they may reflect the affective state of the patient. Countertransference is best recognized and used rather than disdained or ignored. A "totalistic approach," as suggested by Kernberg (1, 9), employs countertransference as a means of extending understanding and yields important information about nonverbal cues, particularly with borderline patients, when the therapist is aware of the potential use of his/her emotional responses as an indicator of the patient's feeling.

IDENTIFICATION AND COUNTERIDENTIFICATION

The patient projects worthlessness, greed, or hostility onto the therapist (4). This projection is a subsidiary form of "splitting," a process by which the ego is protected from conflict by separation of libidinal (good) and aggressive (bad) impulses. The need for projection, for such a low level of defense, reflects the patient's continuous and intense internal struggle against annihilation. Further, there is a related and conceptually separable lower level of defense, a more primitive form of projection—projective identification (16). This particular form of projection is common in borderline characters, who identify and "empathize fearfully" with the persons on whom they have projected their own aggressive internalized objects from the past (17). This is not absolutely different from forms of transference experienced with other kinds of patients, but the intensity and unshakability of the position often resembles the transference seen in psychotic patients (3). The therapist is experienced as an attacking, hostile person, and the patient identifies with the hostility by attempting a sadomasochistic struggle to control the projected impulses that cannot be controlled from within. The therapist often responds with apathy or loss of empathy, ranging from the wish to be distant to quiet thoughts of murder (7). When the therapist responds to the attack with rage, a seesaw battle often ensues.

The therapist's usual attitude during therapy makes him/her vulnerable to narcissistic injury. Attentive focus on the patient and the necessary identification, or "transient trial identifications" (18), often cloud objectivity and apperception of the therapist's own feeling states. Further, the goal of helping the patient makes one more susceptible to the patient's aggression and simultaneously more blind to one's own normal angry response. Counteridentification, a more permanent identification with the patient, occurs as a result of regression from such transient trial identifications. I view counteridentification as a mode of coping with the therapist's anger in response to the patient's assaults. It is a denial of the normal or human response to attack. The therapist needs to accept the inevitability of at least occasional regressions into counter-

[1]Fault is often found with the use of terms that seem to be derived from descriptions of digestive or physiological function. The justification for their use is that they are metaphors and are consonant with the patient's apperception. Borderline characters frequently are intensely self-preoccupied and see themselves as bad, or, defensively, as good only in contrast to others on whom they project their bad parts. As a phenomenologic experience the good and bad do not coalesce; they never perceive themselves as a unity with virtues as well as faults.

identification and understand that awareness of feelings can become an important therapeutic tool. Such awareness and vigilance regarding feelings of anger and apathy aid in maintaining empathy and in recognizing the transient nature of identification; the alternative may be fixity and stalemate.

THE "SECOND EFFORT"

The therapist must feel good about him/herself and separated from the patient in order to continue a helpful dialogue (19), while realizing that he/she is subject to emotional forces that are sometimes too difficult for immediate mastery; that he/she wishes to help as best he/she can, that the patient is defending against a sense of vulnerability rather than being an "aggressive, hostile person." The second effort is formed when one becomes more fully aware of the counteridentification and tendency to continue the reciprocal victim-victimizer interactions. Some therapists deny their anger (7); the second effort taxes the therapist's vigilance and preparedness to see him/herself as subject to some of the same forces that burden the patient. The therapist's "strain" (15), then, is to use those feelings in the interest of the reparative impulse rather than yielding to the tendency to narcissistic retreat (i.e., isolation, loss of empathy, and withdrawal during the therapeutic interaction). There is no way to achieve immunity against such feelings, but it helps to be aware of the necessity of recognizing one's anger in treating borderline patients.

In the course of a therapy hour, counteridentification often replaces empathic response to a patient without the therapist's awareness. When borderline patients accuse me of ineffectiveness, banality, or lack of understanding, I often experience discomfort accompanied by the conviction that the patient is quite correct. On one occasion, my thoughts ran as follows: "I feel that I have not helped the patient, I am repetitious, perhaps I help no one." There are times when I find myself wishing that I could stop treating such patients; I wish they would go away or die. On other occasions, I have thought that I was probably about to catch the flu and would be sick for a few (peaceful) days. It is helpful to subject these feeling states to self-examination. Usually, I discover the patient's sense of negation *within me*.

On one occasion, a patient was in the midst of one of her frequent and lacerating criticisms of my ability. I had "not helped her at all." She had on many previous occasions suggested that we terminate treatment or cut down on treatment time. I quietly suggested that we could discuss the possibility of fewer visits. She cried out in terror, "Don't shout at me—please."

When I suggested that we discuss interruption of her treatment, I felt that it might be best for the patient in that she could be relieved of her hostility toward me: I felt that she might perceive termination as freedom to leave a relationship in which she felt trapped and angry. At a preconscious level, I too felt trapped, defeated, and depressed. I was not totally aware of the reason for my discomfort until the patient ended her lacerating criticism and openly expressed the sense of helplessness, fear, and self-negation that she had projected onto me.

It is very important to understand not only the tendency toward introjection of the patient's negative feelings but the repetitive and fixed way in which the therapist may take these feelings on. It was this phenomenon that prevented me from appropriately clarifying the affect of the patient I have described. I reacted to her feeling state within myself. Later, when I saw this cycle and realized it had happened before, I could offer an appropriate clarification directed toward her underlying self-negation. I could only do this after I appreciated that I was placing back within her the self-negation and helplessness that she had thrust onto me. On subsequent occasions I have learned to point out her self-negation, which is reflected in her negation of me. I can be separate without trying to be rid of her.

The elusive but important issue presented by Malin and Grotstein (17) is that identification is always a part of the more primitive process of projective identification. For patients with borderline characters, projective identification represents an important means of achieving object relationships.[2] My initial agreement with my patient's projection (i.e., my indication that I might be of no help) was a form of projective counteridentification, an assimilation of her projections (4).

I wished also unconsciously to rid myself of the patient, to separate and distance, in order to avoid negative and/or sadistic feelings and to be free of the necessary and wearying self-analytic vigilance. At that, the "I-Thou" relationship ended, at least temporarily. Later, when I was free to scrutinize both of our affective oscillations and became aware of my own anger, I was able to help her examine her projection. Dialogue was then reestablished and our relationship had far less reciprocal negation. This episode also made me aware of my own general impulses and sensitivity to the stress such patients impose on me. A new, positive phase of treatment with a stronger sense of alliance then began. Attention was directed toward the patient's feelings of valuelessness and her anticipation of ridicule, which resulted in cycles of rejection of others and a terror of loneliness that forced her into subservient positions.

With other borderline patients, the therapist can be-

[2]Projective identification is not limited to borderline conditions. It can be seen generally as a potent force in human life. Indeed, altruism and love may have their beginnings in a form of projective identification in which good part objects are projected onto or into another or others. Identification in such cases is with a cathected object that reflects one's own goodness, positive feeling, or ego ideal. Relatedness is achieved in this fashion and is accompanied by a feeling of increased worth. Projective identification with hostile part objects (projected onto another person) may also be seen as an attempt to achieve relatedness or engagement. However, in such cases the identification is hostile, recapitulating the sense of worthlessness that has its origins in earliest relationships.

come "stuck" in what appears to be a totally supportive role. The patient does not change and never gives any sign of hopefulness about the future. There may be little overt anger toward the therapist. Yet in retrospect (after much time—longer, usually, than the therapist wants to realize) the cycle of projective identification and introjection of the patient's negative feelings can be seen in discrete interactions. Often this cycle colors the entire therapy. The therapist is both the victim and victimizer, dragged along in a sense of helplessness and frustration in a situation that mimics aspects of the patient's own life. The therapist also punishes the patient by keeping his/her distance and by avoiding the center of hopelessness and vulnerability. Only by appreciating one's own discontent and its importance can one stop colluding with the punitive forces within the patient; then, helpful treatment can begin.

Collaboration Between Ohio Psychiatrists and the Legislature to Update Commitment Laws

BY VICTOR M. VICTOROFF, M.D.

The author describes how the Ohio Psychiatric Association (OPA) worked with the state legislature to ensure that the revision of Ohio's laws regarding involuntary commitment of the mentally ill reflected what psychiatrists felt to be in the best interests of patients. The OPA was successful in changing the definition of "persons subject to hospitalization by court order," in abolishing suggested 90-day and 180-day limits on the hospitalization of certain kinds of patients, in supporting the participation of psychologists in the admission process after the presence of a medical examiner had been affirmed, and in protecting the confidentiality of private patients' records.

IN THE SPRING of 1975 the Ohio legislature undertook a major revision of the statutes regarding the mentally ill; the revision would accent the need to protect the civil rights of involuntary patients.

Early in March 1975 the leadership of the Ohio Psychiatric Association (OPA) learned that a bill revising the statutes had been assigned to a subcommittee of the Judiciary Committee of the Ohio House of Representatives. Psychiatrists had long been pressing for extended guarantees for patients' rights, but we were concerned that in the enthusiasm to establish protection of civil rights, patients' rights might be sacrificed. Our apprehension was justified. On examining the bill (House Bill 244), we found the following problems:

1. The definition of "persons subject to hospitalization by court order" included only those who were overtly suicidal or homicidal.

2. Allegedly suicidal patients would be discharged after 90 days' hospitalization on the theory that "if their desire to kill themselves continued that long it was either a rational choice and not a product of mental illness, or if a continuing illness, untreatable."

3. Mentally ill persons regarded as nondangerous would be discharged at the end of 180 days "because if no treatment is effective in half a year it is probable it will never be and it is wrong to lock a person up indeterminately . . . if there is no foreseeable benefit and if the person is harmless."

4. Trial by jury would be available on request of the respondent. (Throughout the bill the patient was identified as the respondent.)

5. Psychologists (in tandem with nonpsychiatric physicians) would be authorized to certify regarding mental status in probable cause and full court hearings. There were also a few lines that could be interpreted to allow psychologists to admit, treat, and discharge patients in hospitals.

6. A legal rights service independent of the state's General Assembly, the Department of Mental Health and Mental Retardation, and the Office of the Attorney General would be created; this service would have unprecedented power. It would monitor the fate of all people affected by the statutes. Appointed by the Chief Justice of the Supreme Court of Ohio, the administrator of this legal rights service and his or her staff would be responsible to no one; all they would have to do would be to provide annual reports. All records pertaining to respondents, including those in computerized data banks, were to be available to this legal rights service on demand.

7. The language of the statute could be interpreted to include the availability to the service of charts of patients in private offices. The rights of privacy and privileged communication would thus be suspended for the new advocacy service.

8. The most stringent criterion for legal evidence, "beyond a reasonable doubt," would apply to testimony by witnesses in determining whether a respondent were subject to hospitalization under the statutory definitions. Throughout the bill there was an accent on the least restrictive alternative of care.

RESOURCES OF THE OPA

The resources and experience of the OPA were tested by the proposed bill. We had already employed as executive secretary an attorney with experience in the political process. He has worked on a retainer for us,

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Victoroff is in private practice at 2231 N. Taylor Rd., Cleveland, Ohio 44112.

The author would like to thank Ohio Rep. Harry J. Lehman of Shaker Heights for his sage and dispassionate contribution to this paper; Prof. Michael Kindred of Ohio State University, an honorable opponent in these transactions; and, especially, Rep. Edward J. Feighan of Cleveland, who won our respect as he championed our minority cause before his colleagues on the Judiciary Committee of the Ohio House of Representatives.

doing administrative chores, keeping records, and setting up meetings as well as monitoring the legislature.

The OPA, whose membership numbers almost 500, actively pursues relationships with other mental health organizations. We have called into existence the Ohio Alliance for Mental Health when provocative issues have surfaced. This forum brings together representatives from both professional and citizen mental health organizations. The OPA offers the alliance a temporary chairperson to make arrangements for meetings, establish an agenda, keep constructive testimony flowing, and maintain communication flow among participants.

The OPA also encourages its branch associations to establish their own local legislative committees. We invite the chairperson of the Ohio State Medical Association's Mental Health Committee to attend OPA council meetings, and our president has been reciprocally invited to participate in committee meetings of the Ohio State Medical Association (OSMA). The director of the Ohio Department of Mental Health and Mental Retardation is regularly invited to take part in OPA meetings.

About once a year OPA holds a working meeting with members of the legislature; these meetings range from cocktail parties to two-day retreats. Our members are urged to volunteer for a project called "lunch with a legislator"; each member involved in this program is expected to be a liaison agent for a particular legislator and to keep the legislator informed about issues that concern OPA.

REACTION TO HOUSE BILL 244

When House Bill 244 was presented to the judiciary subcommittee OPA mobilized its resources. Our legislative committee reached out for our natural allies, OSMA's Committee on Mental Health, the Ohio Hospital Association, and the Probate Judges Association. We also attempted to organize the private psychiatric hospitals into a separate legislative action group but ran thin on manpower and time and never consummated the project.

At our legislative representative's summons we made ourselves available on short notice to attend hearings and present our views. We met to plan testimony, devise amendments, and arrive at consensus. On at least one occasion psychiatrists from all parts of the state convened to confront what seemed to be a crisis only to be told that the legislative subcommittee could not meet because it did not have a quorum.

Much of the proposed bill was sound. However, there was so much wrong with it that we had to decide under what conditions we would seek to defeat it, what we could compromise on, and what we could bargain away. The irreducible "no-surrender" issues were the following:

1. The definition of "mentally ill, subject to hospitalization" should include people incapable of caring for themselves who, by reason of mental illness, cannot function in society and, because of their illness, may not realize or cooperate in their need for hospitalization.

2. The statutory limits on the duration of hospitalization should be removed.

3. Psychologists should not be given responsibility for the determination of mental illness without reference to a physician; psychologists should not be allowed to practice in hospitals independent of physicians.

4. The concept of an unsupervised legal rights service answerable to no one and with access to any medical record should be repudiated and resisted.

•We were given two weeks to iron out our differences with the psychologists and advised to come back to the subcommittee with accord. After a futile exchange of correspondence with the psychologists we returned to the committee deadlocked.

An important reason for the intransigence of the psychologists was that they had previously managed to add to Senate Bill 185 the term "licensed clinical psychologist and licensed physician" to the word "psychiatrists" in the definition of those qualified to decide on the mental status of persons alleged to be criminally insane. This bill had been passed unanimously in the legislature without our knowledge. The break in vigilance that allowed the statutory establishment of the equation that one psychiatrist is equal to a clinical psychologist plus a physician was to prove costly in the debate on House Bill 244.

The legislators were not impressed with our testimony that medical students receive an average of 400 hours of training in psychiatry and that only a physician can make a diagnosis of "no medical illness." Nor were they impressed with our concern that psychologists may advise the court wrongly with respect to the care of the patient's needs and thus may cause precious time to be lost determining proper disposition of the patient's case and that the bill would substitute fewer than 1,000 psychologists of uncertain competency for 14,000 physicians who have discharged their responsibility for many years.

COLLABORATION

On May 5, 1975, at a crucial time in the proceedings, the chairman of the subcommittee broke his knee playing baseball. As a result we won almost a month of constructive time. Because the process by which legislative committees operate requires that amendments be proffered by a member who understands the issues and can respond to questions by fellow members we sought out a bright, articulate committee member to help us.

The committee member we sought out advised us to prepare amendments in specific accordance with approved custom, something we had not been previously informed was necessary. When the legislator was con-

vinced of the merit of our position, he sponsored our cause in subsequent meetings of the committee.

As a necessary element in the education of this committee member we invited him to meet two patients on the psychiatric ward of a suburban hospital. Both patients had given their written consent to this visit. One of the patients had been admitted to the hospital after she had hurled a bottle through a picture window in order to break a curse put on her house by a jealous neighbor. The other was a manic-depressive patient who had stopped taking lithium and destroyed a considerable amount of her household furniture before the police took her to the hospital. Both patients admitted that they had been hospitalized against their will but that they belonged in the hospital, trusted their doctor, and expected to be well soon. We pointed out that if the proposed bill had been passed in its unamended form neither patient could have been hospitalized.

By the time the bill moved to the Judiciary Committee hearings we had developed rapport with about half of the members and felt we had a fighting chance. With the aid of powerful testimony from Dr. Moritz, Director of the Ohio Department of Mental Health and Mental Retardation, who said that he would ask the governor to veto the bill if the definition section was not changed, and on hearing our protagonist member's description of his experience at the hospital, the Judiciary Committee accepted our amendment to the definition section of the bill.

Our most earnest effort was then directed toward convincing the committee not to authorize the involvement of the proposed legal rights service with voluntary hospitalized patients. We stressed that privileged communication is not a social indulgence or a casual privilege that merely facilitates commerce between the health professional and his or her patient; it is a sine qua non for the therapeutic process.

Members of the legal aid society unexpectedly admitted that they were uncomfortable about the matter of confidentiality and suggested that amendments be made to allow voluntary patients in private hospitals to decline the services of the legal rights service on their own initiative. We insisted that patients entering a hospital should not have to reassert their constitutional right to privacy.

The bill was reported out of the Judiciary Committee and voted on by the House of Representatives on February 17, 1976. Our critical amendment permitting access to patients' records in privately operated mental hospitals only on the request of the patient was recommended at the last moment. The House approved the bill by voice vote.

DISCUSSION

Considering the four substantive issues on which we were unwilling to compromise, what was the outcome? On the expansion of the definition of mental illness, we got the wording changed. We achieved the abolishment of the 90-day limit for hospitalization of suicidal patients and the 180-day limit for chronically ill "harmless" patients. We gained a weighted decision on the issue of psychologists in that psychologists would not be authorized to practice in hospitals independent of medical supervision, but we were forced to compromise the position of nonpsychiatric physicians, who would now be required to call on a psychologist to collaborate in the examination of patients in probable cause and formal court hearings when a psychiatrist was not available.

We won a split decision in regard to the legal rights service, salvaging the concept that care in private hospitals is not only different from but better than care in public hospitals and maintaining the right to privacy for voluntary patients in private hospitals. The criterion of "beyond a reasonable doubt" was changed to "clear and convincing evidence," and a host of lesser amendments changed this bill to the point that we could at least tolerate the new legislation.

The bill was referred to the Judiciary Committee of the Ohio Senate. Social workers and guidance counselors then demanded the same privileges that the clinical psychologists had obtained. Civil libertarians tried to add an amendment that would require voluntary patients in private hospitals to obtain court approval for surgery, ECT, and other therapies. We debated these changes, and the Senate rejected the modifications. On April 29, 1976, the day before the legislative session ended, the bill was passed by a vote of 32 to 1.

RECOMMENDATIONS

We are convinced by our experience that legislators and the medical profession are now joined in social alliance. Consumer demands, federal money, and judicial decisions require accountability, rules, limits, and standards to be written into the laws that inevitably affect the way physicians practice.

Assuming that an APA district branch accepts the realities of the legislative process, we recommend certain perspectives and actions. First is the appreciation of the importance of time. The psychiatrist must be ready to present his or her case at the convenience of the legislators. There are no accommodations or special courtesies given to medical professionals.

The psychiatric association must be represented at every legislative meeting regarding any relevant bill by the physical presence of knowledgeable members authorized to speak for the association. Delegated legislative representatives should be carefully chosen and meticulously briefed. They must then be given discretion, within stated boundaries, to deal with events as they see fit. The legislature will not wait for the delegates to call for instructions nor will it defer a decision until the organization's executive council meets.

An attorney familiar with medical matters, parliamentary procedure, and the legislative process should be hired on a retainer to watch for legislation affecting

psychiatry, to cultivate friends among the legislators, to be ubiquitous in the corridors of the state capitol, and to advise when to press for passage or to kill various bills. The members of the association should be kept informed about this attorney's work; it will be easier to obtain their acquiescence to the inevitable increase in dues when they realize the costs of representation and the penalties of not having it.

State legislatures vary. District branch officers must determine where the power rests to know how and where to tap into the system. In New York, for example, it rests with the Speaker of the House. In other states, such as Ohio, the power is spread among committee chairmen, who determine agenda, priorities, assignment of bills, and the timing of presentations to the committee.

Certain items of legislation favor working through the executive branch, as we did with the director of the Ohio Department of Mental Health and Mental Retardation and his connection with the governor. The legislator who identifies himself or herself with the psychiatric association should rely on the judgment and views of the association's leadership but will not solicit them. The legislature is a market in which many proposals compete. There is continual competition among issues to establish priorities. Consider that in most states only 1 bill in 10 presented to the legislature in a given session will pass.

Most legislators work in this capacity part-time; they are usually ordinary citizens, particularly in the small states. They reflect a cross-section of the populace. They do not have time to research the issues presented to them; they have to depend on background information, their instincts, and their education.

The political process has to be considered. In Ohio we have taken the attitude that mental health must be nonpartisan; this is a good rule, but it may be necessary at times to depart from it.

Continuing education of key people in the legislature should go on even when the assembly is not in session. Legislators should be invited to meetings of the association as guest speakers.

In dealing with the legislature it is highly desirable to present an "agreed" bill. Legislators want to be free of difficult choices, especially controversial philosophical decisions. It is a relief to them if certain bills and issues loaded with explosive potential slide smoothly through the legislative process because contentious parties have already agreed to the provisions.

Establishing the doctrine of making bridges between the APA district branch and all other mental health organizations within the state and soliciting financial support from our membership, as we have done in Ohio, are adaptational devices for the survival of psychiatry and the practice of medicine in years to come. The process is unending. Immediately after completing work on one bill and one session the leadership must prepare for another.

The cycle can well be identified by a quotation from Edgar Lee Masters' *Spoon River Anthology:*

> Ten thousand times I've done my best,
> And all's to do again.

The Prevention of Tardive Dyskinesia

BY GEORGE E. CRANE, M.D.

The publication of numerous articles on tardive dyskinesia has had little effect on the excessive use of neuroleptic drugs in psychiatric populations. If current prescribing patterns are not drastically changed, larger numbers of patients will be afflicted by conspicuous, sometimes disabling neurological side effects. The risk of permanent neurological disorder can be minimized by monitoring side effects and systematically reducing drug doses in hospitals, outpatient centers, and private practice. However, one should not underestimate the difficulty in implementing such a program in facilities that rely heavily on chemotherapy.

DURING THE last decade numerous articles have been published on tardive dyskinesia. In 1972 and 1973 the package inserts of all neuroleptic drugs were updated to include information on this disorder, and in early 1973 an editorial entitled "Neurological Syndromes Associated with Antipsychotic Drug Use" was published in the *Archives of General Psychiatry* (1) and other reputable medical journals. More and more authors are cautioning physicians to use greater discretion in their administration of neuroleptic drugs to their patients (2–4). Certainly there has been no shortage of clinical information on tardive dyskinesia.

In order to determine whether education would affect the prescribing patterns of physicians, I delivered to the staff of a well-known hospital a lecture in which I emphasized the necessity of reducing the doses of neuroleptic drugs for all patients. When I compared the amount of medication prescribed in 8 representative wards shortly before this talk and 6 months later, I found that the average daily dose had increased from 250 to 252 mg of chlorpromazine or equivalent doses of other neuroleptic drugs. This is a clear indication that the impact of my educational efforts on the prescribing habits of the physician has been nil. The results of this survey cannot be generalized, of course. Yet if an oral communication accompanied by a discussion of a topic of mutual interest is ineffective, I doubt very much that the medical community can be influenced by the more impersonal communications offered by the scientific literature.

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Crane is Clinical Professor of Psychiatry, University of North Dakota School of Medicine, Grand Forks, N.D. His current address is 817 Valley Ave., Solana Beach, Calif. 92075.

EFFECTS OF CURRENT PRESCRIBING PATTERNS ON PATIENTS

Large doses of phenothiazines (2000 mg of chlorpromazine or 80 mg of trifluoperazine) are more likely to produce or aggravate tardive dyskinesia in patients aged 40–55 than are the conventional doses (5). But in older persons the risk of persistent motor abnormalities rises sharply even when relatively small doses (100 or 200 mg of chlorpromazine a day or equivalent doses of other neuroleptics) are taken for over 6 months (6).

It is well known that tardive dyskinesia is the result of the cumulative effects of neuroleptics. The following study provides additional evidence. In 1970 I surveyed the incidence of drug-induced neurological disorders among 900 chronic schizophrenic inpatients (6). Four and one-half years later 221 patients from the original sample were selected for another project, which gave me an opportunity to assess their neurological status and compare it with my observations from the first survey. (The patients' average daily doses of neuroleptics had not changed significantly.)

Table 1 shows that the total number of patients afflicted with tardive dyskinesia, particularly of a severe

type, increased substantially during this period. Since this was not a controlled study the possibility of artifacts cannot be ruled out. For instance, the greater prevalence of tardive dyskinesia at the time of the second survey may simply reflect a greater sensitivity of the methods used to record the severity of the motor disorder. It does not seem likely, however, that severe dyskinesia was overlooked in 11 patients who were found to be symptom free in 1970 and severely affected 4½ years later (see table 1). Thus the number of neurological disorders can only increase if current practices of antipsychotic drug use are allowed to continue.

The large doses of neuroleptic drugs that are now prescribed by most psychiatrists are not only harmful but also unnecessary. In order to prove this I instituted a program of drug reduction in 4 wards housing approximately 160 patients. They were under my supervision for periods of up to 3 years. At the conclusion of this study it was clear that the original dose levels could be substantially reduced for most patients without affecting the general climate of these wards. This study has been reported in detail elsewhere (7).

The next step was a cooperative effort with 3 staff physicians to see whether these results could be replicated in 4 wards over which I had no direct control. The degree of my participation in this project varied. One of the physicians was urged to reduce medication without discussing the merits of this procedure in individual cases. There was much closer cooperation with the other 2 physicians in that we jointly evaluated each patient's behavior in the process of adjusting dose levels. There was an overall decrease in dose levels, but the best results were obtained in an open ward where my participation in the project was the greatest. In general, regardless of the degree of my cooperation, attempts to lower doses were unsatisfactory in wards with a large number of disturbed patients. Most patients continued to be disturbed despite the high doses prescribed to them. Thus the amount of medication prescribed reflected the severity of behavioral aberrations rather than the effectiveness of the treatment.

In conclusion, neuroleptic drugs are not the answer to the problems created by patients with serious psychiatric disorders. A program of drug reduction will not be completely successful unless there are alternative ways of managing such patients.

PREVENTING TARDIVE DYSKINESIA

A maintenance dose of 400 mg of chlorpromazine a day or equivalent doses of other neuroleptics seems to be safe and probably quite effective for most patients. However, for persons over 55, doses should not exceed 150 mg a day. For geriatric patients, doses should not be higher than 75 mg a day (8).

The monitoring of side effects is another essential part of a preventive program. Physicians and nurses

TABLE 1
Number of Chronic Schizophrenic Patients with Tardive Dyskinesia and Parkinsonism in Two Surveys

Side Effect	Group 1 (N=221) 1970	Group 1 (N=221) 1974	Group 2 in 1970* (N=25)
Tardive dyskinesia			
Severe	7	25	5
Moderate	19	36	2
Minimal	19	30	2
Parkinsonism	26	17	4
Parkinsonism and tardive dyskinesia	3	6	1
None	147	107	11

*Group 2 consists of the group 1 patients who had severe tardive dyskinesia in 1974. (Breakdown is by the ratings of tardive dyskinesia at the time of the first survey in 1970.)

can easily recognize drug-induced neurological disorders after a relatively brief period of training. The main problem is that side effects are not adequately recorded. Hence the physician cannot follow the progress of an emerging neurological disorder, nor is he in a position to initiate corrective measures.

The physician should bear in mind that the patient he sees for the first time may have a long history of drug therapy by other practitioners in private offices, clinics, or hospitals. Therefore, it cannot be emphasized sufficiently that the physician should perform a routine neurological examination before prescribing a neuroleptic drug and that he should also record all findings, both positive and negative. The physician should also try to obtain as much information as possible about previous medication. If the patient is already afflicted with a neurological disorder, the importance of gathering these data is obvious from a medical and legal point of view. But even though new patients are symptom free despite intensive antipsychotic drug therapy, their susceptibility to side effects is much greater than that of patients who have never received such drugs. Hence, a more cautious use of neuroleptics is in order in such cases. The form presented in appendix 1 is suggested for the purpose of recording relevant information at intake. On subsequent neurological examinations proper entries may be made in the patient's record whenever drug prescriptions are renewed.

The recommended procedures will permit prompt detection of neurological impairment and immediate corrective action in order to prevent early dyskinesia from becoming permanent. It is doubtful that these measures will completely eliminate tardive dyskinesia, but they may result in an acceptably low incidence of this disorder in the future.

CONCLUSIONS

It is quite obvious that the publication of articles on tardive dyskinesia and the pleas of a few concerned

investigators to use neuroleptic drugs with greater discretion have had little impact on the prescribing practices of physicians. Efforts to improve the quality of patient care by peer review committees, medical associations, and other organizations have been equally ineffective, which is a clear indication that major medical problems cannot be solved by bureaucratic procedures.

The utility of a program of drug reduction in conjunction with an effective system of monitoring adverse reactions cannot be disputed. Nevertheless, one should not underestimate the obstacles that must be overcome when certain practices are based on faith rather than on medical considerations.

Only a more rational approach to psychopharmacological drug use will avoid further regulatory action by federal, state, and local agencies. In addition, a more responsible attitude on the part of the medical profession will prevent harassment by civil liberties groups and will undoubtedly reduce the risk of exorbitant malpractice insurance premiums and the constant threat of lawsuits by the legal profession.

Clinical Research Techniques in Tardive Dyskinesia

BY WILLIAM E. FANN, M.D., JOHN R. STAFFORD, M.D., RUSSELL L. MALONE, PH.D., JAMES D. FROST, JR., M.D., AND BRUCE W. RICHMAN, M.A.

The authors have developed standardized assessment and control techniques designed to provide objective measures of tardive dyskinesia in patients progressing through an experimental treatment program. Standardized videotaping is carried out and blind ratings on the Abnormal Involuntary Movement Scale are made by a team of psychiatrists and neurologists. Other assessments include several measurements of vocal function and a quantitative acceleration profile standardized on normal subjects. Such measures allow quantifiable determination of response to drug treatment and may provide clues to the etiology and definition of the dyskinetic syndrome.

MEDICAL OPINION concerning the precise pharmacological mechanisms involved in the etiology of tardive dyskinesia remains divided, although the implication of altered neurotransmitter substances is rather firmly established. Our own studies and clinical observations tend to confirm the widening belief that what physicians call tardive dyskinesia may be a group of symptomatically similar syndromes, all of which occur as side effects of antipsychotic drugs but which have varying specific etiology, depending on 1) which neuroleptic or combination has been used, 2) the duration of prescription, and/or 3) a poorly defined idiosyncratic predisposition in the individual. Additional information concerning biochemical, neurophysiological, and clinical substrates of the condition is required before we can arrive at a complete explanation of tardive dyskinesia.

A considerable amount of clinical research has been conducted during the last 10 years on the pharmacology and treatment of tardive dyskinesia. Investigators have administered additional neuroleptics, deanol, lithium, amantadine, L-dopa, methylphenidate, physostigmine, and other agents known to affect pertinent neurotransmitter substances; they then attempt to monitor any ensuing clinical remission or increase in dyskinetic symptoms (1–12). The methods of assessing and quantifying pre- and postdrug abnormal movements have included blind and informed ratings of videotapes, direct interviews with patients before and during the experimental trial, a variety of rating scales, and electrophysiological techniques (3, 13–15). The variety of affected areas, the unpatterned nature of the movements, and the tendency of patients to self-consciously limit their dyskinetic movements during ratings present considerable problems in obtaining measurements of symptoms and interfere with accurate assessment of the efficacy of compounds administered in clinical trials for relief of the syndrome.

We have attempted to develop in our laboratory a series of assessment and control techniques for tardive dyskinesia that are intended to provide objective measures of the condition as patients progress through our experimental treatment program. A series of measures rather than a single rating instrument is used as a means of cross-validation within the study. These methods include blind rating of videotapes using the Abnormal Involuntary Movement Scale (AIMS), placebo control, assessment of neuromuscular function as reflected in speech, global assessment by ward staff, and the quantitative acceleration profile, an electronic testing procedure based on the principles of the accelerometer.

VIDEOTAPING

Patients are videotaped in a standard procedure before receiving study compounds, once a week during drug administration, and once a month after discontinuation of the drug. Patients previously diagnosed as suffering from tardive dyskinesia are escorted to a studio within the hospital and seated on a stage. The camera operator follows the order of the AIMS, focusing for one minute each on the patient's face, lips, jaw, tongue, upper and lower extremities, trunk, and global

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Fann is Professor of Psychiatry and Associate Professor of Pharmacology, Dr. Stafford is Assistant Professor of Psychiatry, Dr. Malone is Assistant Professor of Otorhinolaryngology and Communicative Sciences, and Mr. Richman is Instructor in Scientific Communication, Department of Psychiatry, Baylor College of Medicine, Houston, Tex. 77030. Dr. Frost is Associate Chief, Neurophysiology Service, the Methodist Hospital, Houston, Tex., where Dr. Malone is Chief of Speech Pathology. Dr. Fann is also Chief, Psychiatry Service, Veterans Administration Hospital, Houston, Tex., where Dr. Stafford is Director, Drug Abuse Programs, and Dr. Malone is Chief, Audiology and Speech Pathology.

The authors acknowledge the assistance of Elaine Miller, Houston Veterans Administration Hospital, in the conduct of this research, and Nancy Berry, Baylor College of Medicine, in the preparation of the manuscript.

appearance. Patients are also asked to walk across the stage several times for assessment of gait. The videotapes are coded by a research assistant and reviewed by a team of psychiatrists and neurologists at the end of the study. Each segment is given blind ratings on the AIMS for degree of dyskinetic symptomatology. Numerical ratings from 0 (no abnormal movement) to 5 (severe abnormal movement) are analyzed by the Wilcoxin matched-pairs signed-rank test. Interrater reliability is assessed using the Kendall coefficient of concordance.

PLACEBO CONTROL

Although it is unlikely that tardive dyskinesia has a significant psychosomatic component, it is well known that patients can consciously limit their abnormal movements for brief periods of time, particularly when they feel they are being scrutinized. This seriously hinders accurate assessment of medication-related improvement. We use placebo for the first 2 weeks to control our trials of active medications in the treatment of dyskinesia. Patients are videotaped and subjected to the rating procedures used with the active drug, and tests conducted on placebo are rated blind.

SPEECH ASSESSMENT

Assessment of vocal function in dyskinetic patients is based on the premise that individuals afflicted with neuromuscular disturbance will be affected in the very subtle and precise areas involved in speech articulation. It is well known that patients with tardive dyskinesia display prominent bucco-facio-lingual hyperkinesis and discoordination, and it has been postulated that these disturbances are reflected in altered articulative abilities among dyskinetics. It has also been widely recognized that patients who have maintained dyskinetic symptoms for a prolonged period of time develop marked hypertrophy of the tongue, which may reduce the critical ratio between orality and nasality in speech by impeding the passage of air through the oral cavity. It may also be hypothesized that the dysarthria associated with dyskinesia may affect oral-pharyngeal closure, with consequent diminution of speech orality and increased nasality components. The speech tests are designed to provide quantified assessment of the vocal impairment associated with tardive dyskinesia and to reflect changes in impairment over time.

The following speech assessment tests are administered at baseline and repeated at fixed intervals during the drug trial: 1) the Templin-Darley Diagnostic Test of Articulation (16), 2) oral structural and muscular examination, 3) standard reading passage, 4) conversational speech sample, 5) intensity range during conversational speech, 6) softest intensity on sustained vowel, and 7) loudest intensity on sustained vowel.

The Templin-Darley test requires the subject to produce 141 phonemes or blends in the context of a single word. Stimuli are presented visually, either by picture or printed word.

The oral structural and muscular examination evaluates two major areas: nonspeaking motor control and motor control for speech. Breathing, laryngeal activity, tongue mobility, facial muscles, muscles of mastication, palatopharyngeal muscles, diadochokinetic rate for sounds, sound combinations, and articulators are assessed.

The standard reading, the 63-word "Zoo Passage," contains all English sounds except nasals and was designed by Dr. Samuel Fletcher in 1972 (17). Conversational speech is elicited by encouraging the subject to discuss his impression of the Houston Veterans Administration Hospital and of the city of Houston compared with his home town.

A group of six speech pathologists listens to four or five samples of the speech of each patient. Each sample consists of 30 seconds of reading and conversational speech and is presented three or four times in combination with each of the other samples of the patient's speech. Listeners are asked to determine whether they hear normal or deviant speech or voice and to characterize any deviations noted. Imprecision of articulation and breathy voice quality have appeared in our early tests to characterize the speech of patients with dyskinesias.

The intensity tests are conducted using the Tonar-II vocal assessment device developed by Fletcher (17). The Tonar system consists of a sound-separation microphone assembly used to isolate the oral speech component from the nasal, a control and display console, and a reinforcement panel assembly. The microphone assembly is a two-chamber acoustically isolated device with a ceramic microphone used as the receptor in each chamber. The signals from each microphone are amplified within the assembly prior to transmission to the control console. The control and display console consists of a dual-channel analyzer system, a nasality ratio computer, and analog and digital displays for presentation of signal and frequency information.

The primary function of the Tonar is to measure nasality. Nasality in the instrumental sense is the ratio of nasal signal to the sum of the nasal and oral signals, expressed as a percentage. The scale of nasality is from 0 to 100%, and the normal range is 5%–20% if the English nasal consonants are eliminated from the test passage.

A hypernasal condition is said to exist if nasality exceeds 20%, and nasality less than 5% is defined as hyponasal or denasal. Sound and pitch level measurements are included in the system. It is postulated that changes in vocal function and coordination will accompany the onset of drug-related neurological disorders and provide early indicants of impending gross neuromuscular dysfunction or reflect improvement in the dyskinetic condition following treatment within the study protocol.

ACCELERATION PROFILE

The quantitative acceleration profile, which is done with triaxial vector accelerometry, provides a graphic display of the motion characteristics of a particular anatomical site and may be used to observe involuntary motor activity during a resting state or to study movement quality while a subject performs a specific range-of-motion exercise. Motion is detected by a miniature triaxial accelerometer attached to the site being studied. For purposes of monitoring drug-induced parkinsonism and dyskinesia, these areas include wrist, ankles, and chin. Electronic circuitry combines the three outputs in a vector fashion to obtain an absolute magnitude value of acceleration and its first derivative with respect to time. A graphic display of acceleration and acceleration change is provided by a strip chart recorder, and these measures are electronically integrated over a predetermined time interval to obtain values for total change of velocity and total change of acceleration. The latter measures are displayed digitally at the end of a specific observation.

This technique has been evaluated in a group of normal subjects, and baseline data now exist with respect to the various measures and derivations and the expected ranges of normal variation. It is hypothesized that characteristic differences will be apparent in the motion profiles of patients developing drug-induced movement disorders and that these findings will be useful in diagnosing emerging symptoms and monitoring treatment-related changes. Each subject is evaluated in the resting condition and during active exercise.

The active protocol involves abduction/adduction of the left and right upper extremities in a range-of-motion task. The subject is seated in a straight-backed chair placed against a backboard. The subject's midline is centered on a floor-to-ceiling reference line and a set of targets (4-inch-diameter foam rubber spheres) is arranged in space to delineate the designed path for the range-of-motion exercise. All target positions are measured with respect to the reference line and the floor to permit the same test conditions to be used on subsequent visits. The lower target is placed so that the subject is able to touch it with his fingers when his arms are relaxed and falling at his sides, and the upper target is situated above the first so that full abduction of the arm at the shoulder is required to touch it. All subjects are paced at 0.3 repetitions per second by alternately illuminating the two targets. Each test sequence lasts 30 seconds and each arm is tested three times, with short intervening rest periods.

The characteristics of each arm are quantified by use of the following five indices:

1. The simple periodic motion equivalency factor (SPMEF), a direct estimate of the smoothness of motion, is a comparison of the observed ratio of total change of acceleration and total change of velocity with the theoretical ratio, which is calculated from the target dimensions and the pacing rate, assuming that the motion is sinusoidal (i.e., perfectly smooth). Values above 1 indicate the presence of frequency components higher than the fundamental frequency (i.e., the pacing rate); the higher the SPMEF value, the less smooth the motion.

2. The theoretical peak equivalent (TPE) compares the observed average peak acceleration value during each motion cycle with a theoretical sinusoidal model equivalent. TPE values above 1 (the lower limit) provide a measure of the excess acceleration the subject uses in moving quickly from one target to another and is thus an index of the "effort" expended.

3. The theoretical integration of peak acceleration ratio (TIPAR) is a comparison of the observed total change of velocity and the theoretical value that would be expected if the value obtained for average peak acceleration were based on sinusoidal activity. Since a value of 1 would indicate the presence of sinusoidal behavior, deviations from 1 provide an index of actual wave shapes. Because values above 1 are associated with wave forms of less area than their sinusoidal equivalents, the TIPAR quantifies the relative "steepness" of peaks in the acceleration-versus-time tracing.

4. Total change of velocity is simply the total area delineated by the tracing of acceleration versus time. As the name implies, it quantifies velocity characteristics over the time period of the range-of-motion task.

5. Total change of acceleration is the integration of the change-of-acceleration-versus-time tracing. A measure of the irregularity of motion is obtained by quantifying the total change of acceleration and comparing it to the total change of velocity.

The passive portion of the examination involves quantification of spontaneous movements detected at 1) the left and right hands, by an accelerometer attached on the dorsal aspect over the knuckles, 2) the left and right legs, by an accelerometer attached on the lateral aspect of the leg just above the ankle, and 3) the chin, by an accelerometer attached in the midline. During the evaluation of the hands, the subject sits with his arms relaxed and his hands resting in his lap. During evaluation of the legs and chin, the subject engages in a simple task in which he is asked to maintain the points of two pencils in close apposition while the hands are resting in the lap. This maneuver is intended to minimize voluntary suppression of motion in the anatomical site under study. During examination of the legs, subjects sit on an examining table with their legs hanging free.

Quantification of the resting characteristics is based on examination of the tracings of acceleration versus time obtained during fixed 2-minute observation periods. Each spontaneous, involuntary muscular contraction that exceeds a preset amplitude above the inherent noise level of the system is recorded. The results are displayed as histograms, showing the number of movements falling into each of several peak amplitude categories. The results thus provide a measure of the total number of involuntary events occurring in a fixed interval of time as well as a measure of the absolute amplitude of each involuntary event.

ETIOLOGY

Questions involving the biochemical etiology of tardive dyskinesia have been approached through postmortem examination of brain tissue (18, 19) and comparison of dyskinetic features to those of other movement disorders such as Huntington's disease and drug-induced parkinsonism. We have examined the etiological mechanisms in tardive dyskinesia in the context of clinical trials of compounds hypothesized to affect the implicated neurotransmitter systems. By monitoring our patients' responses to the various compounds, we can attempt to interpolate the nature of the biochemical abnormality that appears clinically as tardive dyskinesia. We have administered to several groups of patients the cholinergic substances physostigmine (8) and deanol (3), as well as methylphenidate (7), which stimulates central dopamine and adrenergic activity, and cyproheptadine, which is known to block the activity of serotonin in brain. Responses to each of these compounds and to compounds administered by other investigators have been so varied that we believe more than one neurotransmitter system may be affected and that the neurological event presenting the clinical symptoms recognized as tardive dyskinesia may in fact be any one of a series of neurotransmitter irregularities associated with specific offending agents, dosage schedules, duration of prescription, or poorly defined idiosyncratic factors.

Further elucidation of the roles of acetylcholine, dopamine (20), serotonin (21), and GABA (22) is required for clearer definition of the dyskinetic syndrome, as are epidemiological data comparing the complete medication histories of dyskinetic patients with a matched equivalent sample of patients treated with neuroleptics who have not developed dyskinesia. The differential diagnosis of tardive dyskinesia from Huntington's disease and other hyperkinetic disorders remains difficult, particularly in elderly patients. Development of efficient clinical methods of routinely assaying levels of biogenic amines and their metabolites in cerebrospinal fluid would be useful in making these distinctions and in determining whether one or several neurotransmitter systems are affected in drug-induced dyskinesia. The use of noninvasive computerized axial tomography has been suggested as a diagnostic technique (15) to distinguish individuals with structural brain changes, who would presumably derive little benefit from drug therapy, from individuals who are anatomically intact but suffer alteration of neuronal systems and who would be most likely to obtain relief from drug therapy. This and other novel research techniques represent significant advances in the definition and treatment of tardive dyskinesia and have already provided us with a limited degree of success in ameliorating this otherwise chronic and irreversible disorder.

Effects of Dopamine Agonists in Tardive Dyskinesia

BY ROBERT C. SMITH, M.D., PH.D., CAROL A. TAMMINGA, M.D., JOSEPH HARASZTI, M.D., GHANSHYAM N. PANDEY, PH.D., AND JOHN M. DAVIS, M.D.

The authors used a combined behavioral and neuroendocrinological strategy to investigate the relevance of abnormalities in the brain dopaminergic systems to the pathophysiology of tardive dyskinesia by assessing the effects of apomorphine, a directly acting dopamine agonist, and d-amphetamine, an indirectly acting dopamine agonist, in patients with tardive dyskinesia. Administration of I.V. d-amphetamine increased dyskinetic movements in most patients with tardive dyskinesia, a finding consistent with the dopaminergic hypothesis. Contrary to predictions based on animal models, apomorphine did not increase dyskinetic movements in these patients but instead substantially reduced dyskinesia in some patients. Patients with tardive dyskinesia did not have a greater drop in serum prolactin or a greater rise in serum growth hormone after apomorphine than normal or chronic schizophrenic subjects without tardive dyskinesia.

SOME AUTHORS (1) have suggested that one of the pharmacological abnormalities involved in the pathophysiology of tardive dyskinesia may be a functional supersensitivity of postsynaptic neurons in the nigrostriatal dopamine system induced by chronic neuroleptic administration. The main evidence supporting this suggestion comes from studies in rats, mice, and guinea pigs (2–9). Compared with saline controls, animals withdrawn from chronic treatment with neuroleptic drugs such as haloperidol, chlorpromazine, or clozapine show increased gnawing, stereotyped behavior, circling behavior, or locomotor activity when they are administered directly acting dopamine receptor agonists such as apomorphine or indirectly acting dopamine agonists such as amphetamine; these behavioral responses have been interpreted as evidence for supersensitivity of postsynaptic dopamine receptors.

Recent research has also presented some biochemical evidence consistent with supersensitivity in these animal models after termination of neuroleptics. Experiments by our group and other researchers demonstrated that rats show a greater decrease in indices of dopamine turnover after administration of apomorphine (8, 9), and Snyder and associates (10) also recently reported that dopamine receptors of these rats show increased dopamine binding.

Is the postsynaptic supersensitivity model relevant to the human clinical syndrome of tardive dyskinesia? Some indirect evidence from psychopharmacological studies in patients with tardive dyskinesia is consistent with the postsynaptic supersensitivity hypothesis. When neuroleptic drugs (such as haloperidol) that block postsynaptic dopamine receptors (11) are administered to patients with symptoms of tardive dyskinesia, the symptoms are at least temporarily reduced (12). Other drugs (such as reserpine) that deplete biogenic amines also reduce symptoms of tardive dyskinesia (13). Chronic administration of L-dopa increases dopamine in presynaptic neurons and also increases tardive dyskinesia symptoms (14). However, both L-dopa and reserpine act primarily through their effects on the presynaptic neuron; therefore, their behavioral effects are not directly relevant to tests of a postsynaptic supersensitivity theory of tardive dyskinesia.

We investigated dopaminergic mechanisms in tardive dyskinesia using a combined behavioral and biochemical approach. The effects of the two provocative test drugs that have been used most frequently in the animal studies—apomorphine, a directly acting dopamine agonist, and *d*-amphetamine, an indirectly acting dopamine agonist—were evaluated in patients with tardive dyskinesia. The behavioral strategy included quantitative ratings of changes in symptom intensity, and the biochemical evaluation involved a neuroendocrine strategy in which the effects of apomorphine on two hormones, prolactin and growth hormone, were assessed in patients with tardive dyskinesia and appropriate control subjects. Previous research has shown that dopaminergic influences have an important role in modulating the release of prolactin and growth hormone (15, 16); dopamine agonists decrease prolactin

Presented at the 129th annual meeting of the American Psychiatric Association, Miami, Fla., May 10–14, 1976.

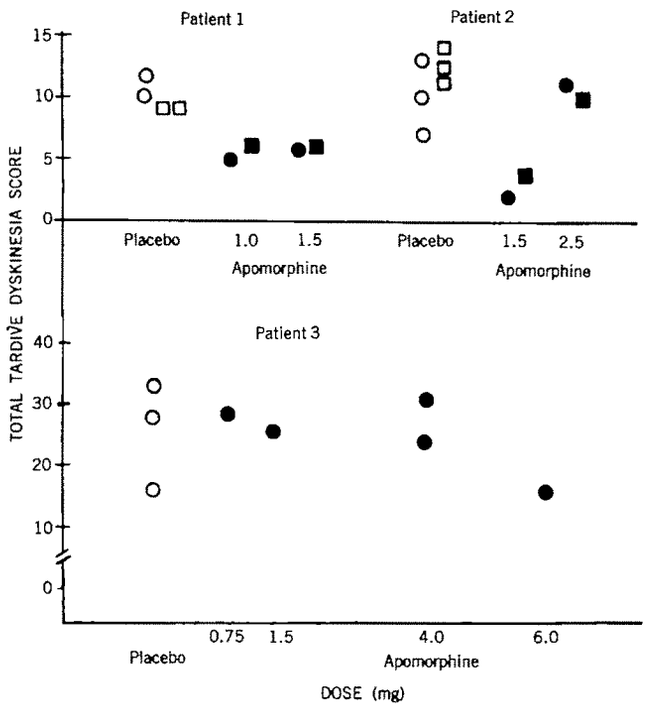
and increase growth hormone (17, 18). If the dopamine agonist tests on animals chronically given neuroleptics, which have been used to demonstrate supersensitivity, can also be applied to analogous tests in patients with the clinical syndrome of tardive dyskinesia, a postsynaptic supersensitivity hypothesis would predict that both apomorphine and *d*-amphetamine should increase symptoms of tardive dyskinesia and that patients with tardive dyskinesia should show a greater fall in prolactin and a greater rise in growth hormone after apomorphine than appropriate control subjects.

METHOD

Patients with tardive dyskinesia were hospitalized on the research wards of the Illinois State Psychiatric Institute and gave informed consent to participate in evaluations and treatment studies of their disorder. Some characteristics of the patient population have been summarized in another article in this section by our research group (19).

Tardive dyskinesia symptoms were evaluated with the Smith Tardive Dyskinesia Scale (20), an observational scale in which many body parts (such as mouth, tongue, cheek, eyes, arms, fingers, waist, legs, feet, etc.) are evaluated for both dyskinetic symptoms (i.e., irregular jerking movements) and extrapyramidal symptoms (e.g., regular tremors, masked face, shuffling gait, etc.) on a 0–4 intensity scale, during a 5–10 minute structured observational rating period. One of us (R.C.S.) developed this scale with the advice of Dr. George Crane. The primary measures used in the statistical analysis were two summary scores derived from sums of ratings on specified body parts: 1) major tardive dyskinesia symptoms, which reflect primarily buccal-lingual symptoms, and 2) total tardive dyskinesia symptoms, the sum of all tardive dyskinesia items. Tardive dyskinesia ratings were done by the principal investigators (R.C.S. and C.T.) and by nurses and staff of the research ward who had achieved a fairly high degree of interrater reliability (r=.80–.95 on total tardive dyskinesia score). Tardive dyskinesia ratings were done routinely several times a week directly on the ward (observational ratings) and also at specific times after acute drug administration. Frequent videotapes (T.V.) of the patient's movements were also made, and these were scored together at a later date. The observational ratings were usually a consensus of two trained raters.

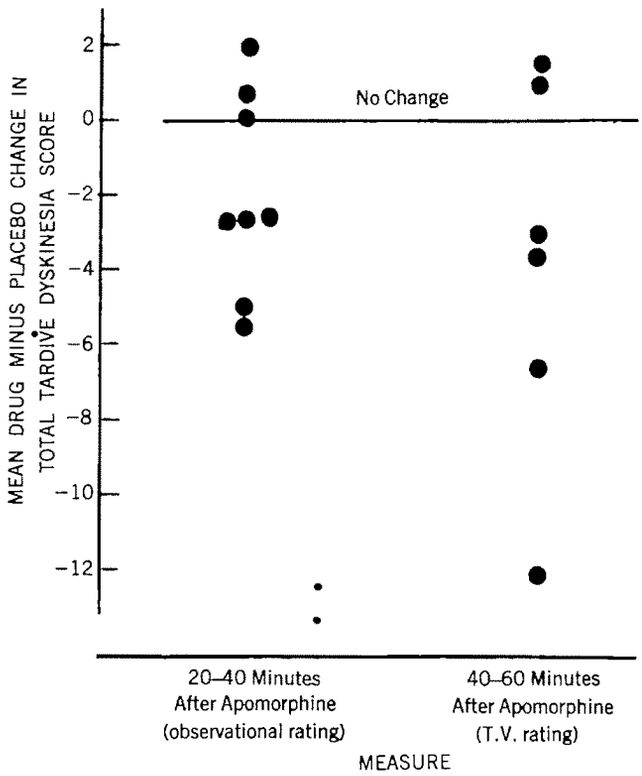
We used double-blind, placebo-controlled procedures to evaluate the behavioral effects of the drugs. All patients had been taken off neuroleptics and tranquilizers for at least 1 week, and most had been off drugs for 3–6 weeks. In the evaluation of the effects of apomorphine, each patient received varying doses of apomorphine (0.75–6.0 mg) or saline placebo subcutaneously at about 9 a.m. (the patients did not eat breakfast the morning of drug administration). Some patients did not complete the full series of doses because they developed side effects (nausea or vomiting) at one of the lower doses. Observational ratings were done 20–30 minutes after medication. In the evaluation of amphetamine's effect, either oral or I.V. procedures were used. In the oral drug protocol, the patients received an elixir of 20 mg of *d*-amphetamine sulfate or placebo solution on two different days, and observational and T.V. ratings were done 30–120 minutes after medication. In the I.V. protocol, 15–20 mg of *d*-amphetamine sulfate or saline placebo was administered intravenously through a scalp vein over a 10- to 15-minute period; blood pressure and psychological responses of the patients were used to help determine rate of administration and whether the drug should be stopped before the full dose had been administered. One patient received additional trials with higher doses of I.V. amphetamine. Observational tardive dyskinesia ratings were made before medication at 5- to 10-minute intervals for 45 minutes during the postdrug period, and again at 1 ½–2 hours after medication.



In the neuroendocrine tests, the patients had not eaten breakfast and were lying in bed with an I.V. catheter inserted in an arm vein. After they had rested for 30–45 minutes, several 5-cc blood samples were drawn and placed in heparinized tubes, and baseline tardive dyskinesia symptoms were scored. The patients then received 0.75 mg of apomorphine subcutaneously, additional tardive dyskinesia ratings were done, and blood samples were drawn over a 3-hour postdrug period. Blood samples were kept on ice and separated into plasma and red cells. Plasma was assayed for growth hormone and prolactin with double antibody radioimmunoassay techniques previously described by Pandey and associates (21) for growth hormone and with National Institute of Arthritis, Metabolism, and Digestive Diseases kits for prolactin.

RESULTS

Behavioral



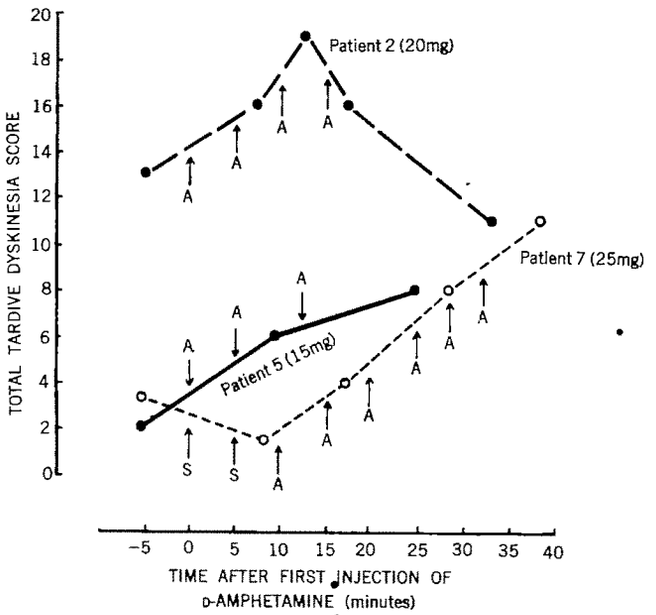
Contrary to our initial expectation, apomorphine did not increase symptoms of tardive dyskinesia. In some patients the drug produced a mild to marked decrease in symptom scores, and in other patients there was little or no change in symptoms. Figure 1 presents more detailed results in a few selected patients. Since there was no simple dose-response relationship for apomorphine effects in the dose range we tested, we computed mean differences between all apomorphine and placebo scores; these drug-placebo differences for 3 patients are presented in figure 2. Most patients experienced emetic effects of apomorphine (nausea and vomiting) at some drug dose, although the dose patients tolerated without side effects varied from 1.5 to 6.0 mg. However, there was no consistent relationship between the effects of apomorphine on emesis and movement symptoms.

FIGURE 1
Effects of Several Doses of Apomorphine on Symptoms of Tardive Dyskinesia*

*Each point represents total tardive dyskinesia score from single ratings performed either at 20–40 minutes or 40–60 minutes after apomorphine. Two or 3 different placebo days (○□) were interspersed between active apomorphine days (○■). ●○ represents observational ratings; □■, ratings from TV tape.

FIGURE 2
Effects of Apomorphine Versus Placebo on Symptoms of Tardive Dyskinesia*

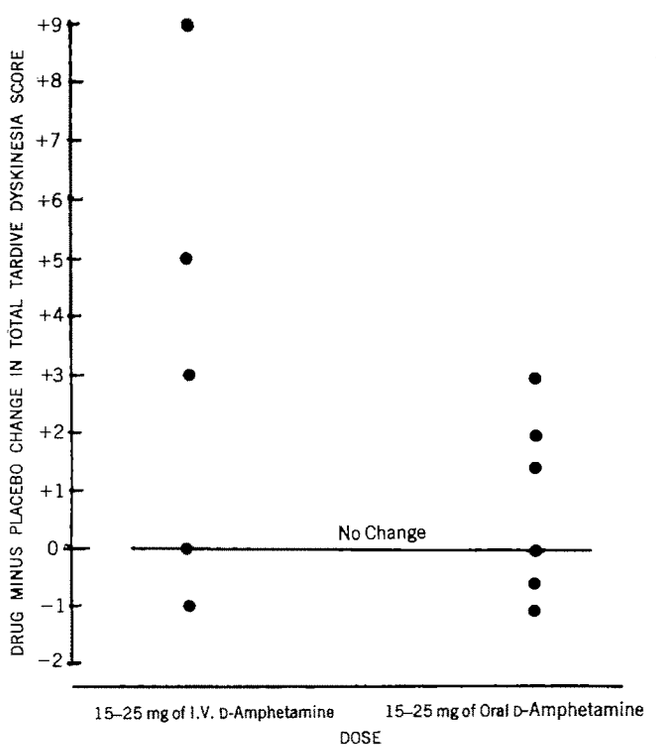
*Each point represents difference of mean scores on 2–5 active apomorphine days minus mean score on 2–5 placebo days. Apomorphine and placebo days alternated in double-blind design.



In contrast to the effects of apomorphine, *d*-amphetamine produced an increase in tardive dyskinesia symptoms in most patients compared with their predrug baseline (see figure 3), although a few patients showed only minimal changes. Compared with their predrug baseline on the same day, 5 of 6 patients showed clear increases in their tardive dyskinesia symptoms after 15–25 mg of I.V. *d*-amphetamine; patient 4 showed a small increase after 40 mg of I.V. *d*-amphetamine. The patients who showed the smallest increase in tardive dyskinesia symptoms after I.V. *d*-amphetamine also had only small or no increases in blood pressure after the drug (e.g., patient 4 had about a 10-mm rise after the 40-mg dose but returned to baseline within a few minutes). However, several of the patients who showed more pronounced increases in dyskinetic symptoms also had only small blood pressure increases. Oral amphetamine also tended to produce increases in tardive dyskinesia symptoms, but the effects of the oral drug were less strong and consistent than the increases with the I.V. drug (figure 4).

It is of interest to note that patients 5 and 6 were reported to have a history of tardive dyskinesia but showed only very questionable subclinical symptoms while in the hospital before the amphetamine I.V. test (total tardive dyskinesia scores of 0–2 on different days). On the basis of the extent of their current symptoms, serious questions were raised among the staff about the accuracy of the history of tardive dyskinesia. In both the patients, however, I.V. amphetamine intensified dyskinetic symptoms in the body areas where they were already present at marginal levels and also brought out additional symptoms in other body areas where there had been no indication of even a mild dyskinetic movement abnormality. The increase in dyskinetic symptoms remitted to baseline levels within 1 ½–3 hours after medication.

Neuroendocrine



The results of the neuroendocrine tests with apomorphine also were not those anticipated on the basis of the simple supersensitivity hypothesis. As shown in figure 5, patients with tardive dyskinesia did not show a greater drop in serum prolactin after apomorphine than either of the two comparison groups—normal or chronic schizophrenic subjects without tardive dyskinesia. Similarly, patients with tardive dyskinesia did not show a greater increase in plasma growth hormone after apomorphine than either of these two comparison groups (figure 6). In fact, for both hormones there was a (nonsignificant) trend for patients with tardive dyskinesia to have slightly lower neuroendocrine responses

to apomorphine than subjects in both of the comparison groups.

DISCUSSION

The behavioral effects of I.V. *d*-amphetamine, which increased symptoms of tardive dyskinesia, are consistent with the interpretation that abnormalities in the brain catecholamine systems are involved in the

pathophysiology of tardive dyskinesia and also have practical clinical implications. However, the effects of apomorphine in patients with tardive dyskinesia did not seem to parallel the behavioral effects that apomorphine has been reported to have in the animal models that have been proposed as possible analogues of this human clinical syndrome. In rats withdrawn from chronic administration of neuroleptic drugs, the administration of apomorphine produces greater stereotyped movements and a greater decrease in dopamine turnover than in appropriate saline controls (2–10); these pharmacological effects have been interpreted as evidence for postsynaptic dopamine receptor supersensitivity. In human patients with tardive dyskinesia, on the other hand, apomorphine tended to reduce dyskinetic movements. The behavioral effects of apomorphine in tardive dyskinesia that we have reported in this paper are similar to the effects of this drug in two other movement disorders, Huntington's chorea (22) and dyskinesia induced by chronic administration of L-dopa in patients with Parkinson's disease (23). Some of the pathophysiology of these two diseases has also been hypothesized to involve supersensitivity of postsynaptic dopamine receptors. Several factors may account for these apparently paradoxical behavioral effects of apomorphine.

1. Recent experimental findings indicate that apomorphine also has important effects on presynaptic dopamine neurons or receptors, decreasing dopamine synthesis, as well as the stimulation of postsynaptic receptors (24–26). These effects make an unambiguous interpretation of our results regarding the postsynaptic dopamine receptor supersensitivity hypothesis in tardive dyskinesia more difficult. The unexpected effects of apomorphine in patients with tardive dyskinesia may, in fact, result from the predominance of presynaptic rather than postsynaptic effects of the drug in the dose range that we used. Consistent with this alternative suggestion, we have recently reported that, at similar doses, apomorphine either reduced or produced no change in psychotic symptoms in some actively ill chronic schizophrenic subjects rather than exacerbating psychotic symptoms, which would have been predicted from a dopamine receptor supersensitivity hypothesis of schizophrenia (27). If a drug could be found that exerted its primary pharmacological effects by direct stimulation of postsynaptic dopamine receptors but did not also have opposite effects on presynaptic dopamine neurons, clinical evaluations with this drug could provide a clearer test of the postsynaptic dopamine receptor supersensitivity hypothesis of tardive dyskinesia. One recent report (28) indicated that the drug bromocriptine, a dopamine receptor agonist that has not yet been reported to have potent presynaptic inhibitory effects, did increase symptoms of Huntington's chorea whereas apomorphine has previously been reported to decrease these symptoms (22).

2. The dose of apomorphine that we administered (0.75–6.0 mg) may have been below that required to produce increases in dyskinetic symptoms. Researchers studying dogs (29) reported that a higher dose of apomorphine was required to produce stereotyped behavior than emesis in this species.

The neuroendocrine strategy, which has been increasingly used in biological psychiatric research, has not been previously extended to the investigation of tardive dyskinesia. We used these neuroendocrine tests as an additional way to assess dopaminergically mediated response in tardive dyskinesia. If patients with tardive dyskinesia had shown a greater change in their prolactin and growth hormone responses to apomorphine than our schizophrenic and normal control groups, this would have provided strong support for the hypothesis of dopamine receptor supersensitivity. However, our negative results showing that apomorphine did not produce greater neuroendocrine responses in these patients do not disprove the receptor supersensitivity hypothesis. The neuroendocrine responses we measured may not be the best biochemical indicator of dopamine-receptor supersensitivity in the nigrostriatal dopamine system, which would be clinically manifested as a movement disorder, but may only reflect functioning of dopamine receptors in the tubuloinfundibular dopamine system (where receptors for dopaminergic activity would influence the secretion of prolactin and growth hormone). Previous research has demonstrated that with repeated neuroleptic administration tolerance develops to the increase in homovanillic acid seen after a single dose of neuroleptics (30, 31) but not to the prolactin response to neuroleptics (32). This may reflect differences in the adaptation of different areas of the brain to repeated neuroleptic administration.

The positive results with *d*-amphetamine may have implications both for theory and clinical testing. Since amphetamine exerts its major effect through release and blockade of reuptake of catecholamines in presynaptic neurons, more attention should be given to possible defects in the functioning of presynaptic neurons in tardive dyskinesia. Of greater clinical significance, however, is our finding that amphetamine could elicit recognizable symptoms of tardive dyskinesia in some patients who had very minimal or subclinical signs of the disease. Since the symptoms of tardive dyskinesia vary considerably from day to day, routine clinical evaluations might easily miss the diagnosis in some of these patients. In cases in which there is some reason (clinical history or length of neuroleptic administration) to presume the possibility of tardive dyskinesia, an I.V. amphetamine test might be a useful additional diagnostic test to help uncover early cases of the disorder. For those patients who demonstrate symptoms of tardive dyskinesia during this provocative test, a more thorough evaluation can be pursued and remedial measures—reduction of neuroleptic doses, extended drug holidays, and therapeutic trials with drugs that might decrease tardive dyskinesia symptoms—could be instituted to try to prevent the progression of the disease.

Cholinergic Influences in Tardive Dyskinesia

BY CAROL A. TAMMINGA, M.D., ROBERT C. SMITH, M.D., PH.D., STEPHEN E. ERICKSEN, M.D., SIDNEY CHANG, M.D., AND JOHN M. DAVIS, M.D.

The authors conducted placebo-controlled double-blind studies of physostigmine, choline, and deanol in 12 patients with tardive dyskinesia. Physostigmine and choline both had a positive therapeutic effect on tardive dyskinesia, but the authors note that interpretation of these results is not entirely clear because they found that the sedation effect of physostigmine may nonspecifically reduce the intensity of tardive dyskinesia symptoms. Deanol was not found to be effective in this group of patients; the authors suggest that this drug should not be assumed to be generally effective unless effectiveness is verified by a large placebo-controlled double-blind study.

THERE IS BOTH basic and clinical evidence suggesting that the cholinergic as well as the dopaminergic system may be involved in extrapyramidal movement disorders (1). Diseases like parkinsonism, Huntington's chorea, Gilles de la Tourette's syndrome, and tardive dyskinesia respond with movement exacerbation or remission to cholinomimetic and cholinolytic agents. The familiar example is Parkinson's disease, in which movements worsen with drugs that increase brain acetylcholine effect (e.g., physostigmine) and are benefited by anticholinergic drugs (2, 3). Studies in experimental animals demonstrate a mutual antagonism between cholinergic and dopaminergic neurons within the neostriatum (4–6); these preclinical studies substantiate inferences made from the observed human pharmacology.

Tardive dyskinesia has been hypothesized to be a dopamine-supersensitive disease (7). Gerlach and associates (8), Fann and associates (9), and Klawans and Rubovits (10) found that physostigmine, a cholinomimetic agent, benefited symptoms, but Gerlach and associates and Klawans and Rubovits also demonstrated that two anticholinergic drugs, biperiden and scopolamine, aggravated tardive dyskinesia movements. A preliminary report from Davis and associates indicated that oral choline used in a precursor loading strategy alleviated tardive dyskinesia (11). Deanol, a postulated but controversial acetylcholine precursor, has been used in the treatment of tardive dyskinesia. Many uncontrolled studies and single case reports detail therapeutic trials of deanol (12–18); some report a positive therapeutic effect. We are not aware of any double-blind placebo-controlled studies validating the clinical impression that deanol helps tardive dyskinesia.

This paper reports results from double-blind placebo-controlled trials of cholinomimetic agents. Physostigmine was used in an acute single dose trial to assess the response of tardive dyskinesia movement to a cholinergic agent. The acute effect of an I.V. dose of physostigmine may indicate the potential efficacy of the treatment of tardive dyskinesia symptoms with chronic cholinergic agents. Chronic administration of deanol was evaluated because of the reports of its efficacy and its purported cholinergic actions. Since there is a body of evidence from animal studies that oral choline does indeed increase brain acetylcholine (19–21), we also carried out a therapeutic trial of oral choline.

SUBJECTS AND METHOD

Twelve patients with tardive dyskinesia were included in this study. The majority came from long-term mental health facilities; 2 were referred from the community. Specific characteristics of the population are summarized in table 1.

On admission to the study the patients were withdrawn from all medication and allowed to be drug-free for 2 weeks (patient 5 continued to receive 100 mg of phenytoin sodium [Dilantin] three times a day). Each gave voluntary consent to the procedures. Since the whole protocol consisted of a number of different acute and chronic drug trials, the sequence was arranged so that there was a 5–7-day drug-free period following any chronic dose of medication and a 2–3-day period following any single-dose drug trial.

The tardive dyskinesia (TD) rating scale used was an

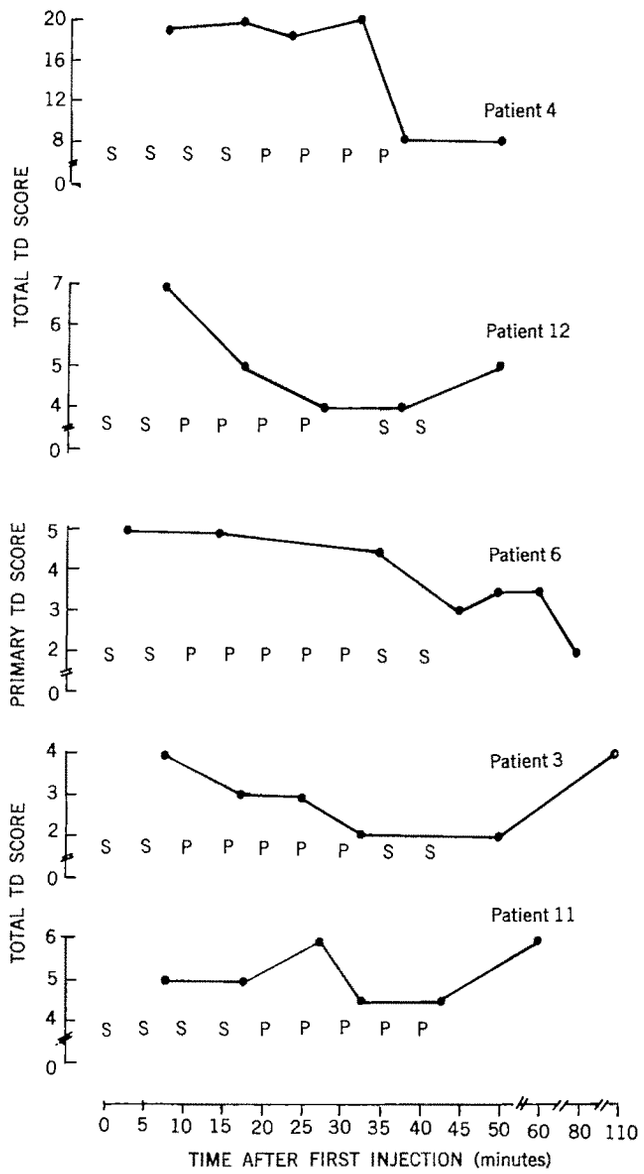
TABLE 1
Characteristics of the 12 Tardive Dyskinesia (TD) Patients Studied

Patient	Sex	Age	Psychiatric Diagnosis	Areas of Most Prominent TD Symptoms	Areas of Other Prominent TD Symptoms
1	Female	68	Chronic schizophrenia	Mouth, tongue, eyes	Hands, feet
2	Female	63	Chronic schizophrenia	Hands	Mouth
3	Female	57	Chronic schizophrenia	Mouth, tongue, waist	Hands
4	Female	33	Schizophrenia; mental retardation	Face	Hands
5	Female	49	Chronic schizophrenia	Mouth	Hands
6	Female	59	Chronic schizophrenia	Mouth, tongue, face	Feet
7	Female	59	Chronic schizo-affective schizophrenia	Mouth	Feet
8	Female	72	Chronic schizophrenia	Face	Hands
9	Female	73	Chronic schizophrenia	Mouth, tongue, face	Hands, feet
10	Male	52	Chronic schizophrenia	Hands, feet	Mouth
11	Male	34	Chronic schizophrenia	Hands	Tongue, face
12	Male	25	Schizo-affective schizophrenia	Face	Waist

observational scale in which movements of specific body parts were rated from 0–4; the TD scale rated both parkinsonian and tardive dyskinesia movements (see the article by Smith and associates in this Special Section of the *Journal*). The scale was developed by one of us (R.C.S.) in collaboration with Dr. George Crane. Patients were rated at least three times a week by trained raters who had an interrater reliability of .80–.95. During the initial evaluation period ratings were done daily and videotaping was done twice a week. We continued to videotape during acute and chronic drug trials at critical times and rated them in series at a later time. We found that evaluating videotapes in this manner fostered a focus on the comparative change in movements.

Three drugs that have been purported to affect central cholinergic mechanisms (deanol, choline, and physostigmine) were used with behavioral evaluations. Deanol was evaluated in a chronic schedule with a double-blind placebo-controlled design in doses beginning at 500 mg a day and increasing to 1250 mg a day over a 3-week period. Daily ratings were done in the morning and afternoon and twice-weekly interviews were conducted and videotaped.

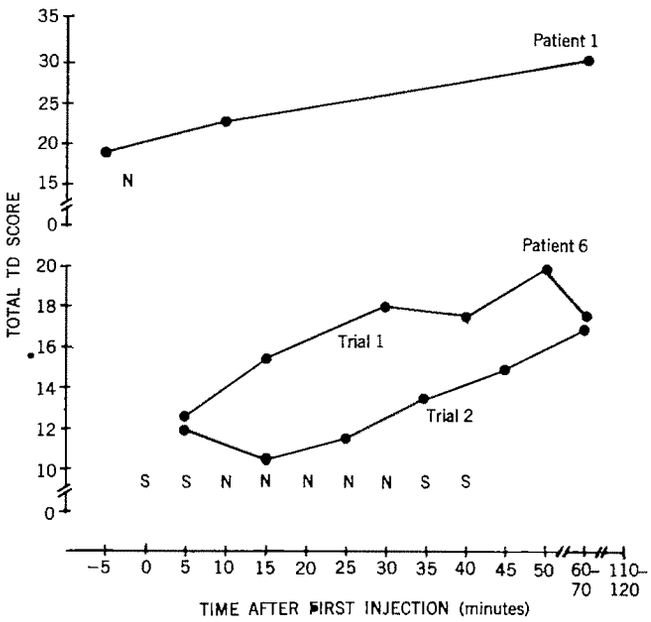
Choline was used in a preliminary nonplacebo trial with a limited number of patients. The drug was given orally in doses beginning at 3 g a day, increasing to 18 g over a 3-week period. Ratings were done daily and videotaping twice weekly. Blood samples were collected for choline levels and prolactin values before each dose increase.



Physostigmine was given in an acute dose. Sixty minutes before the test the patient was given 1 cc of methscopolamine as a peripheral cholinergic blocker. Before the study the patients rested in their rooms for a number of hours. The procedure entailed inserting a butterfly catheter into a forearm vein with a syringe of heparinized saline attached; the patient was given 30 minutes to acclimate to the test procedure before beginning. Physostigmine was then administered in a .5-ml I.V. bolus every 5 minutes with a variable number of initial injections of sterile saline. Up to 2.0 mg of physostigmine was given; the drug injections were stopped before patient discomfort rose as evaluated by the nonblind observer. One of us prepared and gave the medication and remained nonblind; another rated the movements throughout the test and remained blind to the drug given and to the number of initial saline injections. Using the same clinical method, I.V. neostigmine and I.V. methohexital sodium (Brevital) were given as control drugs, one to control for peripheral cholinergic action and the other for sedation, respectively.

Physostigmine

Physostigmine, a central acetylcholinesterase inhibitor, was tested to document previous reports of the effect of this drug in reducing symptoms of tardive dyskinesia. As shown in figure 1, each of 5 patients had some decrease in movements within 10–20 minutes of active drug administration; this ranged from 20%–80% suppression of predrug levels. These data are consistent with previously reported studies, which generally show that physostigmine reduces dyskinetic movements in a tardive dyskinesia population. Neostigmine, a drug that has only peripheral acetylcholinesterase activity, produced no effect on the movements of 2 patients (see figure 2).



During the course of the study our attention was drawn to the effect of an activation/sedation factor on tardive dyskinesia movements. The response of one patient (patient 6) to physostigmine necessitated this consideration. Her movements were initially suppressed with physostigmine, but on repeated testing with electromyography (EMG) (a test that includes repetitive pinprick-like stimulation) the expected movement diminution was blocked (see figure 3). This result suggests that the stimulation of the EMG test counter-

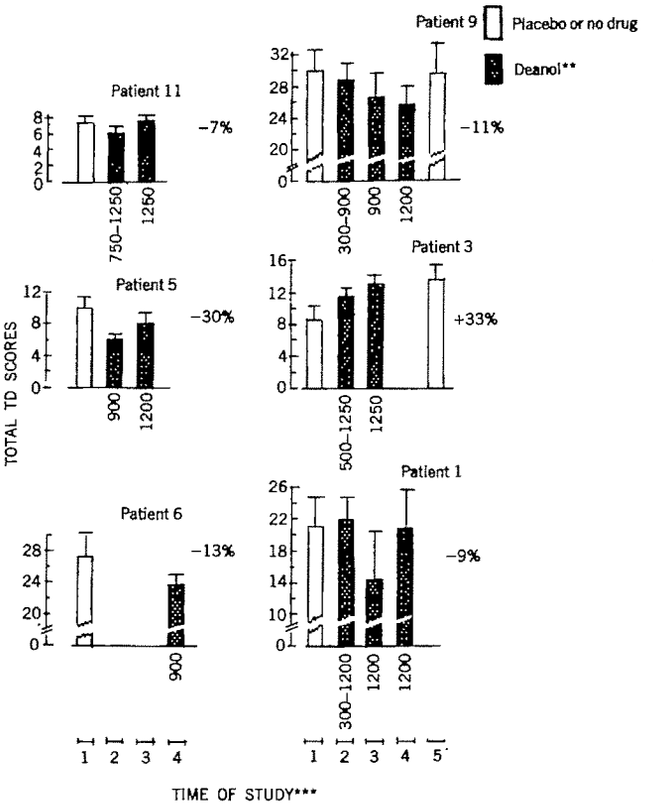
acted the physostigmine effect and, furthermore, that some of physostigmine's effect might be due to the sedative properties of the drug. Other data also indicated that symptoms of tardive dyskinesia might fluctuate with activity level. It is known, for instance, that tardive dyskinesia movements disappear with sleep. Furthermore, in a survey of symptoms of 198 patients in a state hospital population conducted by one of us (R.C.S.) a positive relationship was found between patients with a higher activity level and those with greater dyskinesia symptoms. Therefore, we wondered whether some of the physostigmine effect in reducing tardive dyskinesia symptoms could be due to its sedative properties.

To test this possibility, further I.V. methohexital sodium, a short-acting barbiturate, was used as a control for sedation with the same clinical protocol. The methohexital-induced sedation caused a similar fall in the TD scores of 3 patients; this fall coincided with methohexital's sedative effect (see figure 4).



That the sedative properties of physostigmine may play a role in the suppression of tardive dyskinesia movements appears to be a previously unconsidered factor. It can be added, however, that our clinical observation seems to be able to distinguish between movement remission with physostigmine and with methohexital. We found that the stimulation of talking to the patients rather than just observing them in a

FIGURE 4

drowsy state could distinguish between the movement suppression with physostigmine and that with methohexital. With the methohexital-sedated patients such verbal arousal caused their movement remission to disappear; however, with physostigmine sedation arousal did not readily diminish the movement suppression.

In summary, it has been shown that physostigmine reduced tardive dyskinesia movements in this population of 12 patients by 20%–80%. We found a similar degree of movement remission with methohexital sodium, however; this makes the interpretation of the physostigmine data less clear. Previous studies have not controlled for physostigmine sedation. Although it is probable that physostigmine suppresses tardive dyskinesia movements, delineation of the mechanism—whether by sedation or specific cholinergic activity—needs continued careful evaluation.

Deanol

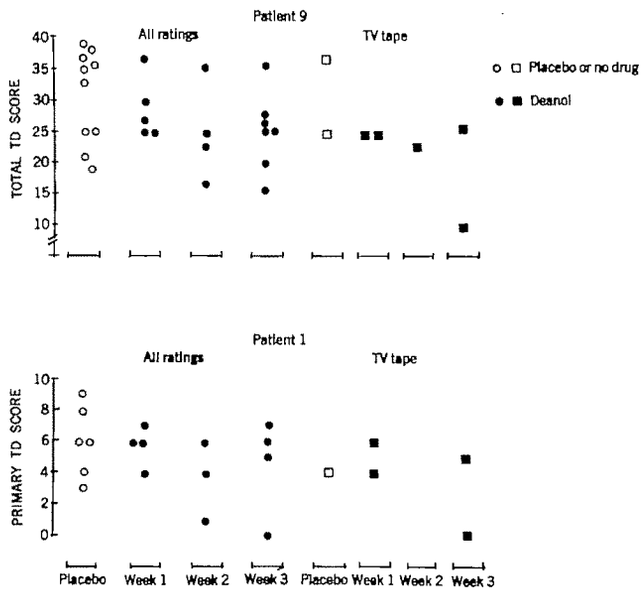
Our results show that deanol did not improve tardive dyskinesia to any substantial degree in the 6 patients who received it. Figure 5 gives the total TD scores for each of the 6 patients averaged for each drug and placebo week. The percent differences in the TD scores between the average of the deanol weeks and the placebo week is indicated to the right of each graph. Although deanol produced a variable reduction in TD symptoms in some patients, exacerbation occurred in others. The symptom reduction that did occur in some patients did not persist with continued treatment and did not appear to be dose related. When we looked at primary symptoms alone (buccolingual-masticatory), we also found no overall beneficial effect of deanol.

What is particularly striking in deanol's effect is the variability in movement ratings on a day-to-day basis. Figure 6 illustrates the range of TD scores in 2 patients who were taking 500–1250 mg of deanol a day and underlines the wide day-to-day variability in TD symptoms. Our conclusion is that the effect of deanol on reducing the symptoms of tardive dyskinesia is not great in the doses used in this study.

Choline

In a preliminary nonblind trial of oral choline in 4 patients with moderate to severe TD symptoms the data indicate some therapeutic effect. Two of the 4

FIGURE 6
Week-to-Week Variability in TD Ratings of 2 Patients Receiving 500–1250 mg of Deanol a Day



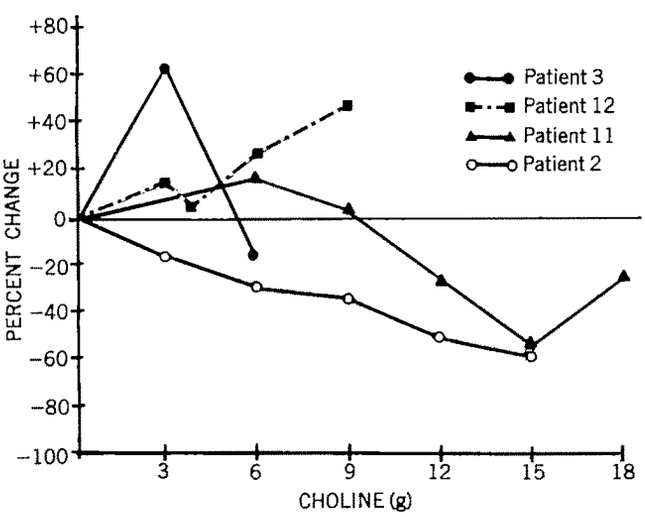


FIGURE 7
Percent Change from Total Baseline TD Scores in Response to Oral Choline in 4 Patients*

*Patient 12 became agitated and depressed, patient 3 became depressed, and both were withdrawn from choline. Patient 11 and patient 2 continued in the study to a therapeutic dose range.

patients showed a trend toward improvement at doses higher than 6 g a day (see figure 7). Unfortunately, administration of the drug had to be stopped in 2 patients due to depression before an adequate dose was reached. In neither of these patients was any substantial improvement noted. Patient 12 was agitated by the depression, which likely exacerbated his tardive dyskinesia movements. We have previously suggested that drugs which increase central acetylcholine may cause depression (22). That this depression was a side effect of oral choline treatment is supported by two factors: 1) the depression remitted with drug withdrawal, and 2) atropine reduced the depressive symptoms while the patient was receiving choline. Depression could have been a predicted side effect of cholinomimetic drug treatment according to the cholinergic-adrenergic balance theory of depression (23). This mood change with choline also tends to confirm the central site of action of choline in humans. Our preliminary findings of therapeutic benefit with choline in tardive dyskinesia need placebo-controlled trials before a definitive statement can be made about its therapeutic effect.

DISCUSSION

There is evidence both from our work and from others of a cholinergic influence in tardive dyskinesia. Our study shows that physostigmine and choline benefit tardive dyskinesia, but the interpretation of these results is not entirely clear because of a methodological variable that surfaced during the study, namely, that sedation may nonspecifically reduce the intensity of tardive dyskinesia symptoms. This observation surfaced serendipitously, as detailed above, when EMG testing was done during a physostigmine test and the expected movement suppression did not occur. These results indicate that sedation may have been a factor in previously reported studies with physostigmine. In our opinion future studies of tardive dyskinesia must include a sedative control for drugs with sedative properties in order to separate the nonspecific movement suppression due to sedation from the specific anti-TD action of a cholinergic agent.

However, on the basis of clinical evidence, we suspect that physostigmine produces an effect beyond sedation because the movement-suppressant physostigmine effect persisted even with arousal, whereas with methohexital this was not the case. Our preliminary findings with choline tend to support the idea of positive therapeutic efficacy of cholinergic agents in tardive dyskinesia. We began using choline as a long-term cholinomimetic agent because of evidence that it increases central acetylcholine levels. Our preliminary results indicating a positive therapeutic effect, although suggestive, are not sufficient to draw definitive conclusions about the general therapeutic efficacy of choline in tardive dyskinesia. Control studies are needed to document choline effect. Our clinical observation of severe depression in 2 patients warrants continued careful observation.

The findings with deanol, as tested in this placebo-controlled double-blind design, failed to confirm previous nonblind trials of the drug that suggested a treatment effect of deanol in tardive dyskinesia. There are a number of important methodological artifacts that may introduce limitations into the interpretation of results from uncontrolled trials of treatment regimens in tardive dyskinesia. First, it has been shown that there is a

large placebo effect with any treatment regimen used in tardive dyskinesia. In previous work with amantadine we found a 50% decrease in tardive dyskinesia symptoms in an uncontrolled study; later controlled studies with amantadine showed that this decrease was a placebo effect (24, 25). In addition, studies with tardive dyskinesia patients frequently include positive environmental changes as a necessary accompaniment to movement assessment (for example, increased staff contact or transfer to a well-staffed research ward), all of which generally alleviate movements. There is a second important reason why controlled studies are necessary. Although tardive dyskinesia symptoms are often permanent, there is a certain spontaneous remission rate following neuroleptic withdrawal. Obviously, this spontaneous remission factor can confound drug response results.

These reasons make it imperative that a double-blind methodology be used in all drug studies in tardive dyskinesia. Deanol use is further complicated by the fact that its pharmacological action as an acetylcholine precursor is not yet firmly established; there continue to be conflicting data as to its action (18). Therefore, our largely negative results with deanol may not be strong evidence against the cholinergic influence in tardive dyskinesia because deanol is not a confirmed acetylcholine precursor.

In summary, although deanol may be effective in treating isolated patients, we can say that the drug should not be assumed to be more generally effective unless this is verified by a large double-blind placebo-controlled study.

Normal regulation of extrapyramidal function may depend on a sensitive balance between dopamine neurons and acetylcholine fibers in the basal ganglia. Previous clinical studies have demonstrated the association of acetylcholine with dopamine in extrapyramidal movement disorders. We have provided data in this study that add both to the pharmacological characterization of cholinergic influences in tardive dyskinesia and to the evaluation of therapeutic agents. The importance of working out the effects of cholinomimetic agents lies in the potential contribution of chronic cholinergic drugs to the treatment of tardive dyskinesia.

Electrophysiological (H-Reflex) Studies of Patients with Tardive Dyskinesia

BY JOHN W. CRAYTON, M.D., ROBERT C. SMITH, M.D., DAVID KLASS, M.D., SIDNEY CHANG, M.D., AND STEPHEN E. ERICKSEN, M.D.

The authors studied the H-reflex recovery curves of 31 schizophrenic patients with tardive dyskinesia in response to acute administrations of apomorphine, amphetamine, or physostigmine and compared them with the curves of chronic schizophrenic patients without tardive dyskinesia and normal volunteers. Their most unexpected finding was the absence of an H-reflex in 9 of the 31 patients with tardive dyskinesia. They also found a relationship between severity of tardive dyskinesia and the value of the facilitatory peak H_x: patients with more severe tardive dyskinesia symptoms had significantly higher values for H_x.

TARDIVE DYSKINESIA is a disabling disorder that increases the morbidity associated with chronic psychotic illness. Despite the intensified interest in this disorder in recent years, there is as yet no consensus about its etiology or underlying pathophysiology, nor have there been consistent results with numerous treatment approaches taken by various investigators. Tardive dyskinesia has been improved in some patients by treatment with agents that reduce the efficacy of dopaminergic transmission, such as haloperidol (1), reserpine (2), and manganese (3), and by substances that enhance cholinergic activity, such as physostigmine (4–7), deanol (8), and choline (9). However, results are not consistent, and some patients continue to be refractory to all treatment.

It seems possible that if more were known about the underlying pathophysiology of tardive dyskinesia, treatment could be tailored to the specific disease process. With this possibility in mind, we initiated an electrophysiological study of this disease in an effort to more carefully delineate possible underlying pathophysiological mechanisms. Our approach has been to assess the excitability of the spinal alpha motoneuron pool, since this has been shown to be altered in a variety of movement disorders (10). Furthermore, we have shown that some patients with schizophrenia have altered spinal reflex excitability patterns (11, 12). We wished to determine if chronic schizophrenic patients who also had tardive dyskinesia could be distinguished from those without tardive dyskinesia and from normal subjects.

SUBJECTS

Our subjects were 31 patients with a diagnosis of chronic schizophrenia who also had tardive dyskinesia. Twenty-three of the patients were long-term inpatients at Manteno State Hospital, Manteno, Ill. The other 8 patients had been admitted to a special research unit at the Illinois State Psychiatric Institute (ISPI) for clinical evaluation and treatment of tardive dyskinesia. The 31 patients were identified for the study through a survey of the incidence of tardive dyskinesia in the Illinois state hospital system carried out by one of us (R.C.S.). Data for these 31 patients were compared with data for chronic schizophrenic patients without tardive dyskinesia at Manteno State Hospital and with data on normal healthy volunteers. Voluntary consent to the procedures was obtained from all patients.

METHOD

Patients were rated as to tardive dyskinesia (TD) and parkinsonian symptoms as described in this special section of the *Journal* by Smith and associates. Patients were divided into three groups according to whether they received high, medium, or low TD scores on the scale they describe. Patients with high ratings had total TD scores of more than 10; medium, 5 to 9; and low, less than 5.

Spinal monosynaptic reflex testing was carried out by the procedure described by Hugon (13). The patient reclined in a large easy chair with his or her leg

FIGURE 1
H-Reflex Recovery Curve for 19 Normal Volunteer Control Subjects*

*The principal features of the curve studied are the initial return of recovery (H_o), the "secondary facilitatory" peak (H_x), and the following trough (H_y).

extended and flexed at an angle of approximately 30°. The I-A afferent sensory fibers were stimulated with a bipolar surface electrode placed in the popliteal fossa; the reflex activity was recorded by surface electrodes placed over the distal tendon and belly of the soleus muscle. Recruitment curves were generated for each patient by gradually increasing the stimulus intensity and measuring the amplitude of the M or direct muscle response and the H or reflex response (14).

The alpha motoneuron excitability recovery cycle was determined by giving paired stimuli (S_1S_2) at delays of between 50 milliseconds and 5 seconds at a stimulus intensity that gave a near-maximal H-response. The ratio of H_2 to H_1 was determined at each stimulus delay for from 3 to 5 determinations at each point. For purposes of statistical comparisons, three principal features of the recovery cycle were studied: H_o, which was the S_1S_2 delay time at which there was an initial return of excitability; H_x, the maximum H_2/H_1 value between 100 and 300 milliseconds; and H_y, the lowest value for H_2/H_1 in the epoch between 300 and 600 milliseconds' delay. (See figure 1.)

Much of our interest centers on H_x, which is increased in patients with Parkinson's disease (10, 15, 16) and reduced in some schizophrenic patients (12). The peak H_x is thought to be partially influenced by descending supraspinal influences; there is also some evidence that it is affected by altered dopaminergic tone (17, 18).

Selected patients at ISPI were treated with acute administrations of apomorphine, amphetamine, or physostigmine. The subjects treated with apomorphine were studied within 1 to 2 hours of the administration of the drug. The patients studied during the physostigmine administration were studied continuously during the repeated injections of 5 mg of physostigmine or saline at 10-minute intervals over the course of 1 hour.

TABLE 1
Presence or Absence of H-Reflex in 30 Schizophrenic Patients with Tardive Dyskinesia

TD Score Status	H-Reflex	
	Absent	Present
Low (N=7)	0	7
Moderate (N=8)	1	7
High (N=15)	8	7

RESULTS

Absence of H-Reflex in Tardive Dyskinesia

Nine schizophrenic patients with tardive dyskinesia failed to have any H-reflex activity (see table 1). In 1 of the 31 patients the presence or absence of an H-reflex was equivocal because the amplitude of the response was similar to background electrical activity. For the 30 subjects in whom the presence or absence of H-reflex activity could be unequivocally determined the absence of H-reflex activity was highly correlated with TD score: 8 of the 9 subjects who lacked an H-reflex had high TD scores; the ninth had a moderate TD score. All of the patients with low TD scores had H-reflexes ($\chi^2=8.0555$, $p<.02$).

In order to determine whether the absence of an H-reflex was a reflection of the effect of dyskinetic movements of the patient at the time of the study we reevaluated 3 patients at times when they showed less movement. Each patient repeatedly failed to show any H-reflex response despite all efforts to elicit one by moving the stimulating and recording electrodes and by facilitation of the reflex via the Jendrassik maneuver (19).

H-Reflex Recovery Cycle

An important difference between our normal volunteer control subjects or the schizophrenic control subjects without TD and TD subjects was the greatly increased run-to-run and test-retest variability in the TD patients. The coefficient of variability (SD×100) for the normal subjects for a set of 5 determinations of H_x was in the range of 4%–8%. Therefore, the recovery cycle is a highly constant neurophysiological feature in normal subjects. In contrast, the coefficient of variability range for TD subjects was 9%–109% (mean, 43%). Some of this variability was undoubtedly due to dyskinetic movements that affect spinal reflex pathways, but the variability was not substantially different when subjects were tested on days when they had high or low TD ratings. Furthermore, there was no consistent relationship between TD scores and the coefficient of variability. In fact, 3 of the subjects with the highest TD scores had low coefficients of variability.

Recovery cycles of motoneuron excitability were studied in the 22 TD patients who had H-responses (including the 1 patient whose response was equivocal). Comparative analysis of H_o, H_x, and H_y values of the

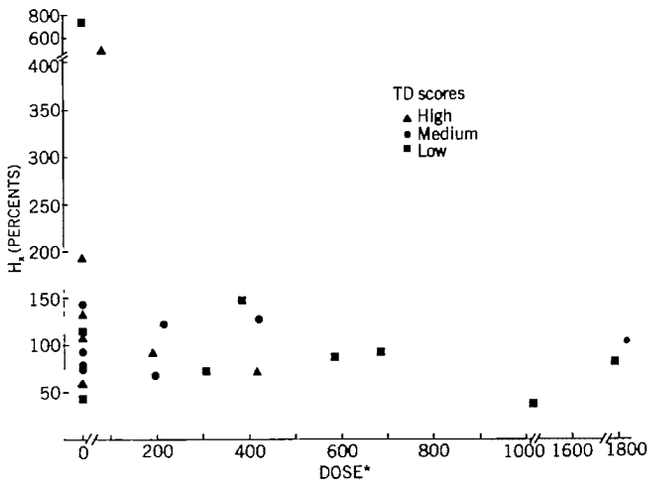
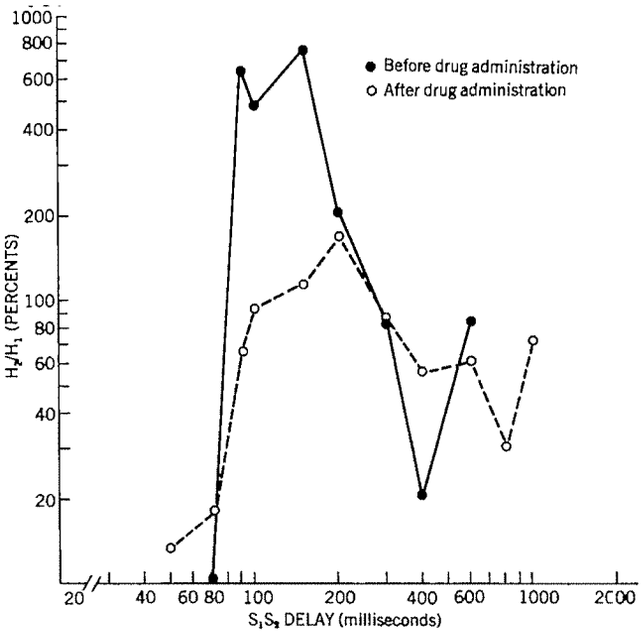
FIGURE 3

H-Reflex Recovery Curves for 4 Schizophrenic Patients with High TD Scores*



*Note the great variability in the curves and the differences between these curves and the one shown for 19 normal subjects in figure 1. Also note the generally higher values for peak H_x in these 4 patients.

recovery cycle between these TD patients and 19 control subjects is shown in table 2, and the values of H_x are displayed in figure 2. Examples of H-reflex curves of 4 schizophrenic patients with high TD scores are shown in figure 3. Chronic schizophrenic patients had lower values for H_x than control subjects, but patients with TD had higher values. Even when the two extreme values of 747 and 488 were excluded from the analysis, two-tailed t tests suggested that the patients with high TD scores differed significantly from both normal control subjects and chronic schizophrenic patients without TD (see table 2).



Previous studies of schizophrenic patients (11, 12) have indicated that H_y is of little discriminative value because of its great variability. Similarly, in this study we found no significant relationships between H_y and TD scores. Mean values of H_y in patients with TD were similar to those for normal subjects and chronic schizophrenic patients without TD. It should be noted, therefore, that the significant separation of values be-

FIGURE 4
H_x Values and Medication Dose for 31 Schizophrenic Patients with TD, According to TD Score

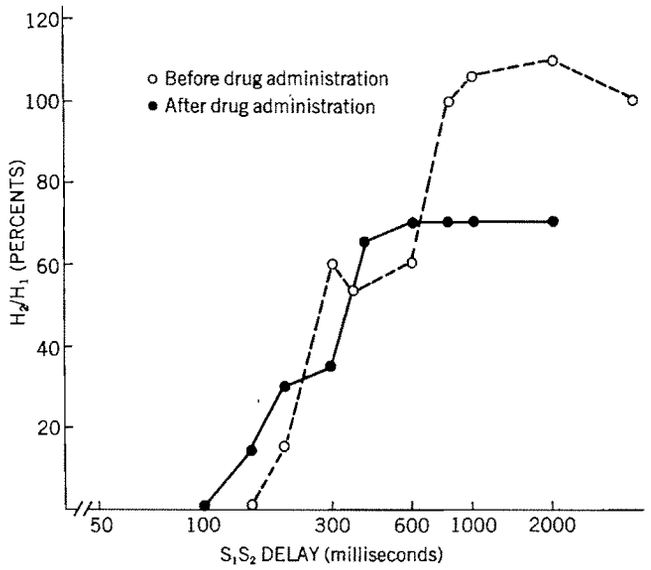
*The most prominent change is a reduction in the value for the peak H_x.

tween schizophrenic patients with and without TD occurs in only one part of the recovery cycle.

Medication Effects

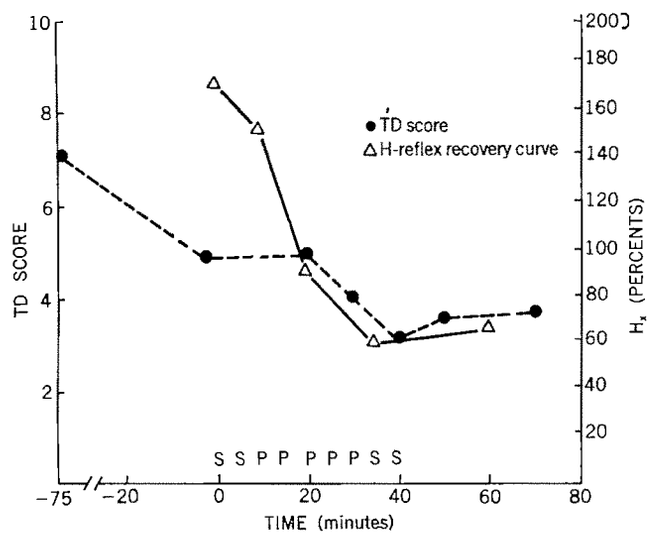
For the experimental group as a whole there was no significant relationship between recovery curve or presence or absence of an H-reflex and current medication or total phenothiazine equivalents during the patient's lifetime. Nor was there a significant correlation between the amount of phenothiazine and TD scores in the whole group. However, if only the patients receiving psychotropic medication are considered, there was a significant correlation of higher drug doses and lower TD scores. The relationship of TD scores to H_x and current medication is illustrated in figure 4. As discussed above, H_x tended to be higher in patients with high TD scores. Figure 4 illustrates that dose of current medication may also be a contributing variable. Six of 7 patients with high TD scores and 6 of 7 with medium TD scores were receiving less than 250 mg of chlorpromazine or equivalent per day ($\chi^2=6.61$, $df=2$; $p<.05$).



We therefore sought a relationship between H_x and dosage. Six of 16 patients with H_x values greater than 120 (38%), including the 2 patients with very high H_x scores, were receiving less than 250 mg of chlorpromazine or equivalent per day, while only 2 of 7 patients with H_x values greater than 120 (29%) were receiving more than 250 mg of chlorpromazine or equivalent per day. Although not statistically significant, these data may suggest a trend toward lower H_x with increasing dosage in these patients.

To test the hypothesis that tardive dyskinesia is a disorder of receptor supersensitivity to dopamine, selected patients were given infusions of the dopamine agonists amphetamine and apomorphine. The patient whose H-reflex recovery curve is shown in figure 5 had been admitted to the unit with a presumptive diagnosis of tardive dyskinesia, but she had little in the way of objective signs of the disorder. During the infusion of amphetamine her excitability curve shifted markedly downward, from 747 to 166 (see figure 5), and she developed marked signs of tardive dyskinesia. In this case the patient had a markedly abnormal recovery curve in the absence of clinical signs of tardive dyskinesia. Dopamine receptor stimulation induced florid TD signs, while at the same time motoneuron excitability as measured by the H-reflex was reduced.

Dopamine receptor stimulation with apomorphine in the patient whose recovery curve is shown in figure 6 also produced a reduction in the value for H_x. Before the infusion this patient had a value for H_x of 110%, but after infusion it dropped to 76%. There was no appreciable change in this patient's clinical TD scores during the infusion.



The contribution of cholinergic mechanisms to TD and H-reflex measurements was assessed by studying patients before and during administration of physostigmine. The patient whose recovery curve is shown in figure 7 showed a small drop in TD scores during physostigmine infusion. This patient's H_x showed a marked drop during the infusion that approximately paralleled the drop in TD scores. The same patient was also studied after treatment with 900 mg of deanol a day for 2 weeks. There was little change in the recovery cycle following deanol treatment. Similarly, there was little change in the patient's TD scores during that time. Deanol in this subject appeared to have little effect on either spinal reflex excitability or on the TD score.

FIGURE 6
Effect of Infusion of 4 mg of I.V. Apomorphine on the H-Reflex Recovery Curve of a Schizophrenic Patient with TD*

*In this patient there was a reduction in the curve values starting at about 600 milliseconds; note that the entire curve is shifted to the right in this patient; the pre-drug-administration H_x occurs at about 1000 milliseconds instead of at the normal 100–300 milliseconds.

FIGURE 7
Effect of Physostigmine Infusion on the H-Reflex Recovery Curve and TD Score of a Schizophrenic Patient with TD*

DISCUSSION

Previous attempts to treat tardive dyskinesia have relied primarily on a clinical description of the dyskinesia and certain hypotheses about the underlying pathophysiology of tardive dyskinesias. The present study was undertaken to determine if a delineation of neuromuscular pathophysiology might define specific abnormalities in the disorder and electrophysiologically characterize certain groups of patients who might be specifically responsive to certain medications. Our data indicate that there is considerable heterogeneity of the electrophysiological findings among the patients diagnosed as having tardive dyskinesia. In some patients we failed to elicit an H-reflex. Others showed alpha motoneuron excitability alterations, with a tendency for extremely high values of H_x.

The absence of an H-reflex in 9 of 31 patients, all but 1 of whom had high TD scores, was an unexpected finding. In more than 60 normal control subjects and more than 250 schizophrenic patients without TD we have yet to find a subject in whom an H-reflex could not be elicited. An absent H-reflex may occur for several reasons. First, it may be an indication of a peripheral neuropathy. Ioku and associates (20) found that a significant percentage of patients with peripheral neuropathy had extremely small or absent H-reflexes. We found no clinical evidence for peripheral neuropathies in these patients, but in previous studies we have shown that schizophrenic patients have an increased incidence of degenerative changes in motoneurons (21, 22) and that they have slowed conduction velocities. According to a paper being prepared by Goode and associates, schizophrenic patients also have reduced numbers of distal motor units.

However, another possible explanation for an absent H-reflex is that the reflex is suppressed by excessive inhibition via spinal or supraspinal mechanisms (17). Further studies of various inputs to the spinal monosynaptic reflex, such as gamma motoneuron activity and the activity of Renshaw circuits, may clarify the role of these inhibitory mechanisms in tardive dyskinesia.

A third possibility to be considered in explaining the absent H-reflexes is that the absence is related to the dyskinetic movements themselves and not to some basic underlying pathophysiological process. It is known that movement alters motoneuron excitability (23, 24). However, there are several lines of evidence that would argue against this formulation. First, those patients studied repeatedly at times when they had high and low TD scores did not show any tendency to afford a correlation between the amount of movement and the H-reflex elicited. Second, chronic schizophrenic patients with considerable hyperactivity have H-reflexes. These include patients with so-called hyperponesis, or baseline electromyographic activity in muscle in the absence of apparent movement (25). Third, the Jendrassik maneuver, which involves brisk movement of the upper extremities and is a means of enhancing spinal reflex activity, did not potentiate H-reflexes in those patients who had no H-reflex. Similarly, since Jendrassik-maneuver potentiation of spinal reflexes is based on upper extremity movement, one might expect that spontaneous movement in TD patients would potentiate the reflex response and could not be an explanation for the absence of an H-reflex.

The major finding in our examination of the H-reflex recovery curve was a relationship between severity of TD and the value of the facilitatory peak H_x. When compared with normal volunteers or chronic schizophrenic control subjects, patients with high TD scores had significantly higher values for H_x. Arguments similar to those outlined above have suggested that the increased values for H_x are not simply related to an increase in alpha motoneuron excitability.

In patients with Parkinson's disease there is an increase in the value for H_x that tends to return toward normal in patients treated either by thalamic surgery or by L-dopa (26). Some patients with chronic schizophrenia tend to have low values for H_x, and these low values can be reversed with phenothiazine medication (7). These data, taken together, suggest that the facilitatory peak H_x is at least partially under the control of a dopaminergic influence, with the height of the peak inversely related to dopaminergic tone. This formulation is supported by results with amphetamines and apomorphine, both of which tended to reduce H_x in the patients studied.

However, these data are not easily compatible with the hypothesis that tardive dyskinesia is due to supersensitivity of dopamine systems in the basal ganglia. If H_x reflects the activity of dopamine systems, then low values of H_x would be associated with high TD scores. Our findings were just the opposite. It is possible that an additional neuronal influence mediated by other neurotransmitters, such as acetylcholine or γ-aminobutyric acid (GABA), are implicated in TD pathophysiology. Physostigmine infusion in the patient whose recovery curve is shown in figure 7 tended to reduce the value for H_x in parallel with the time course of reduction of the TD score.

It is apparent from these studies that there is considerable heterogeneity both clinically and neurophysiologically in tardive dyskinesia. It seems likely that a number of different abnormalities of neurotransmitter systems, including dopaminergic, cholinergic, and others, are involved in its development. Our studies have described certain neurophysiological characteristics of subjects with TD and the effects of dopamine and acetylcholine agonists on these factors. However, there is good evidence that each neurotransmitter has a variety of functions in the CNS. Dopamine acts as both an excitatory and an inhibitory transmitter in the basal ganglia, according to microiontophoretic studies (27), and acetylcholine appears to exert both an excitatory and an inhibitory effect at functionally different receptors in the brain (28). Therefore, it should not be surprising if the administration of a drug that increases dopamine blockade, for example, would have a variety of physiological effects based on blocking both dopamine excitation and inhibition.

No simple view of dopamine activity in tardive dyskinesia is compatible with the various electrophysiological and clinical findings. Further studies of TD patients may delineate certain subpopulations of patients who respond selectively to one or more pharmacological agents and contribute to the early identification of patients at risk for the development of serious neurological impairment as a result of psychotropic drug use.

The Relationship Between Parkinsonism and Tardive Dyskinesia

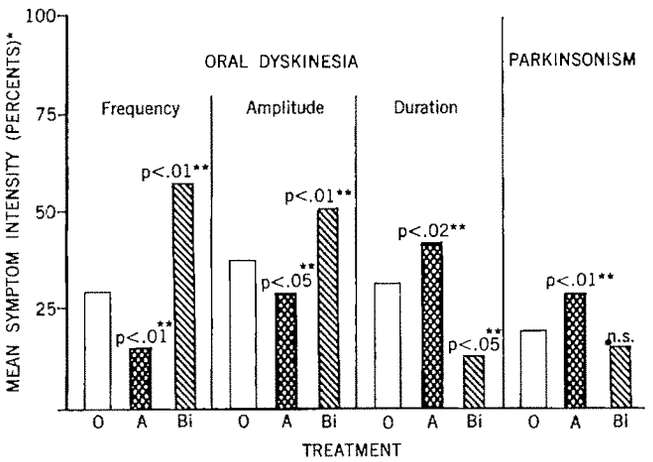
BY JES GERLACH, M.D.

The author analyzes parkinsonism and hyperkinesia in psychiatric patients with tardive dyskinesia before and during treatment with α-methyl-p-tyrosine (AMPT, a dopamine antagonist), biperiden (an acetylcholine antagonist), and baclofen (a GABA agonist); and in patients with paralysis agitans and L-dopa-induced hyperkinesia. AMPT and baclofen had similar influences on oral dyskinesia, resulting in reduced frequency, unchanged or slightly reduced amplitude, and increased duration of each movement. The author concludes that: 1) reduced dopaminergic activity may be the primary pathogenetic background for tardive dyskinesia; 2) dopaminergic hypersensitivity and/or cholinergic hypofunction is necessary before hyperkinesia breaks through; and 3) the neurotoxic effects of neuroleptics may be associated with age-dependent changes in nigrostriatal regions representing oral innervation.

IT HAS OFTEN been stated that the literature on neuroleptic-induced neurological side effects lacks precision and uniformity of description and classification (1–3). This apparent difficulty can be explained; although the neuroleptic-induced disturbances of movement can be roughly classified as acute dystonia, parkinsonism, and tardive dyskinesia (4), in reality they are far from being separate, well-defined syndromes. There is a considerable amount of both clinical and pathogenetic overlap. In an attempt to shed light on this problem we studied the relationship between parkinsonism and hyperkinesia in 1) neuroleptic-treated patients with tardive dyskinesia before and during treatment with α-methyl-p-tyrosine (AMPT, a dopamine antagonist), biperiden (Akineton, an acetylcholine antagonist), or baclofen (Lioresal, a γ-aminobutyric acid [GABA] agonist), and 2) patients with paralysis agitans and L-dopa-induced hyperkinesia.

Presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

At the time this work was done Dr. Gerlach was Staff Psychiatrist, Department E, Sct. Hans Hospital, Roskilde. He is now Staff Psychiatrist, Department of Psychiatry, Rigshospitalet, 9, Blegdamsvej, DK-2100 Copenhagen, Denmark.



TARDIVE DYSKINESIA DURING ANTIDOPAMINERGIC AND ANTICHOLINERGIC TREATMENT

Tardive dyskinesia is mainly localized in the oral area as the so-called bucco-linguo-masticatory syndrome (2, 5, 6). These oral dyskinesias may be described with respect to the following movement elements: frequency (or degree of hypermotility when frequency cannot be measured), amplitude, and duration of each separate tongue protrusion and/or mouth opening (7). The relationship among these elements differs from patient to patient. At times the tongue protrusions are rapid and rhythmic (representing the real hyperkinetic movements of tardive dyskinesia) and at times they are slow, prolonged and almost continuous (more related to parkinsonism).

We studied these movement elements and the degree of parkinsonism in 24 psychiatric patients with neuroleptic-induced tardive dyskinesia (7). During the whole study the patients continued with their previous psychopharmacological treatment. Four g/day of AMPT (an inhibitor of catecholamine synthesis) was given for 3 days, and 12 mg/day of biperiden (an acetylcholine blocker) was given for 3 weeks. The study was carried out with crossover and a blind evaluation of the neurological condition with the help of videotape.

As shown in figure 1, AMPT significantly reduced the frequency (or the hypermotility), whereas biperi-

den increased the hypermotility. The effect of AMPT on the amplitude varied; in 9 cases the amplitude was decreased, in 13 cases it was unchanged, and in 2 cases it was increased. The reduction in amplitude occurred in patients who showed increased parkinsonism following AMPT; the increase occurred in 2 young patients who showed no signs of parkinsonism following AMPT. Biperiden significantly increased the amplitude of oral tardive dyskinesia. The duration of each tongue protrusion or mouth opening was increased by AMPT in 6 cases; in the other cases duration was unchanged. In some cases the total protrusion time was decreased because of a decreased number of protrusions. Biperiden, as would be expected from its effect on motility, significantly reduced the duration of each protrusion.

Sixteen of the 24 patients had shown obvious signs of parkinsonism during previous treatment. In 14 of these 16 patients tardive dyskinesia and parkinsonism occurred simultaneously. AMPT slightly but significantly increased the parkinsonian score, with an aggravation of all classical parkinsonian features (bradykinesia, rigidity, tremor, and salivation). Biperiden had no significant effect on parkinsonism.

This study suggests the following:

1. AMPT, primarily through an inhibition of dopamine neurotransmission, reduces the frequency of tardive dyskinesia. This corresponds to results obtained with other dopamine inhibitors (6, 8–10).

2. Anticholinergic antiparkinsonian drugs increase both the frequency and the amplitude of tardive dyskinesia (11–13).

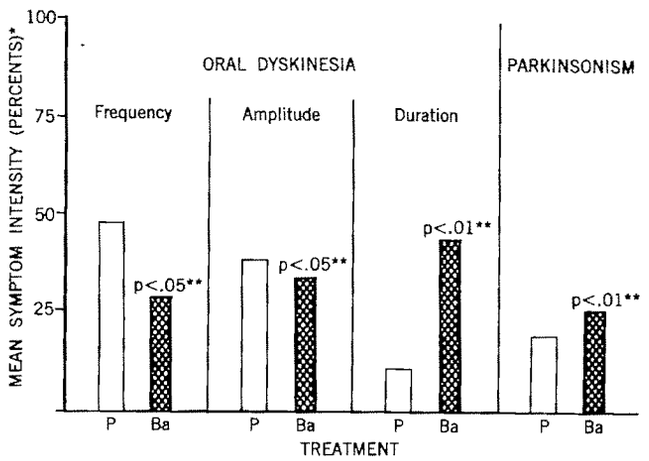
3. AMPT leaves the amplitude unchanged or only slightly reduced; furthermore, AMPT often increases the duration of each separate tongue protrusion or mouth opening. This leads to the conclusion that tardive dyskinesia may be determined primarily by a functionally decreased activity of the dopaminergic system and that the hyperkinetic movement element does not break through until so-called dopaminergic hypersensitivity develops or until anticholinergic treatment is started (7).

This study also shows that tardive dyskinesia and parkinsonism often coexist in the same subject (see also 13, 14) and that patients under long-term treatment with neuroleptics often show signs of parkinsonism that are partly refractory to anticholinergic treatment (15). Although in some cases parkinsonian symptoms may be irreversible (16), they are less obtrusive than those of tardive dyskinesia.

TARDIVE DYSKINESIA DURING BACLOFEN TREATMENT

Traditional inhibitors of dopaminergic neurotransmission (receptor blockers and inhibitors of storage or synthesis) may suppress tardive dyskinesia but may at the same time accentuate the real pathogenetic process behind it (6, 7). New forms of treatment for this late complication of neuroleptic therapy are therefore strongly indicated.

It has recently been shown in animal experiments that GABA agonists can inhibit impulse flow in the nigrostriatal dopaminergic pathways (17, 18) and counteract neuroleptic-induced increases in dopamine turnover (19, 20). There is, therefore, a pharmacolcgical basis for supposing that GABA-stimulating drugs such as beta (*p*-chlorophenyl)-GABA (baclofen) would be able to ameliorate tardive dyskinesia.



We have substantiated this supposition in a double-blind crossover clinical study. Eighteen chronic psychiatric patients aged 47–79 years (median 66) were treated in a randomized sequence with baclofen and placebo. Baclofen and placebo were each given for 3 weeks; effects were evaluated with the aid of videotape at the end of each phase.

The study showed that baclofen (given in doses of 20–120 mg/day, median=75 mg) had both antihyperkinetic and parkinsonism-eliciting effects. Figure 2 shows the average score of patients on three movement elements of oral dyskinesia and parkinsonism. Frequency was reduced in 10 of 18 patients and unchanged in 8. Amplitude was reduced in 8 patients and was unchanged in 10. The duration of each mouth opening was increased in 9 patients and unchanged in 9.

This pattern of response to baclofen corresponds quite well to that of AMPT (see figure 1) and is in accordance with the observation that, from a biochemical point of view, baclofen acts somewhat like AMPT, namely, by inhibition of dopamine neurotransmission (20).

Two-thirds of the patients in this study showed obvious signs of parkinsonism together with tardive dyskinesia. Baclofen slightly but significantly increased

FIGURE 2
Oral Dyskinesia and Parkinsonism in 18 Patients During Treatment with Baclofen (Ba) and Placebo (P).

*Mean percentage of the maximum possible score on the rating scale used (7).
**By Wilcoxon test for paired differences.

parkinsonism; bradykinesia was aggravated in 4 patients, rigidity in 2, tremor in 5, and akathisia in 5.

Baclofen, however, has more disturbing side effects. Sedation, muscular weakness, and confusion were observed in half of the patients. These side effects, which appear particularly in elderly patients, sometimes begin before the antihyperkinetic effect, thus limiting the drug's usefulness.

Therefore, it must be concluded that baclofen has more theoretical than practical therapeutic interest. Further research efforts must concentrate on finding by animal experimentation other GABA agonists without these side effects (i.e., with a more selective action on the GABA receptors of the basal ganglia) and clarifying on the clinical level whether GABA agonists may potentiate the antipsychotic effect of receptor blocking neuroleptics (see 20) and thereby make it possible to reduce the dose of these neuroleptics, as has been done by using AMPT (21, 22).

PARALYSIS AGITANS AND L-DOPA-INDUCED HYPERKINESIA

It is well known that the choreoathetoid movement disturbances often seen in parkinsonian patients treated with L-dopa are of the same type as those seen in neuroleptic-induced tardive dyskinesia (23, 24). The only difference is that tardive dyskinesia is primarily limited to the oral area, whereas L-dopa hyperkinesia usually has a more general distribution. An examination of the localization and intensity of L-dopa hyperkinesia and parkinsonian symptoms shows an independent course of development of oral and extraoral hyperkinesia that suggests the need to distinguish between dyskinesia in the two regions (25).

Oral hyperkinesia shows an increasing rate of occurrence and intensity with age, independent of the degree of parkinsonism and extraoral hyperkinesia. This suggests that age-related phenomena facilitate the development of oral hyperkinesia. The occurrence in older subjects of spontaneous hyperkinesia (senile dyskinesia) involving primarily the oral region (26) supports this view. Pathological studies have demonstrated the presence of a characteristic somatotopic organization of the substantia nigra, the striatum, and their internuclear connections (27, 28). Thus, when neuroleptic-induced tardive dyskinesia involves the oral region almost exclusively, it is reasonable to presume that the possibly irreversible neurotoxic effect of neuroleptics consists of an accelerated progression of age-related changes in the oral somatotopic area of the basal ganglia.

When hyperkinesia of the extremities first appears and parkinsonian symptoms disappear, the hyperkinesia is positively correlated with the severity of the parkinsonism in the respective extremities. This holds both for the patient population as a whole, in which hyperkinesia of the extremities is most pronounced among younger patients, most disabled by parkinsonism, and for the individual patient, in whom hyperkinesia is most pronounced in those body segments most affected by the disease.

This supports the hypothesis that a primary dopaminergic deficiency lies behind hyperkinesia and suggests a causal relationship between parkinsonism and tardive dyskinesia. The biochemical and neurohistological nature of this relationship, including an explanation of the fact that not all parkinsonian patients treated with L-dopa or all neuroleptic-treated psychiatric patients develop hyperkinesia, is not yet fully clarified. Particular problems in this area include the biochemical processes underlying postsynaptic hypersensitivity (especially the importance of the dopamine-sensitive adenyl cyclase), the implications of the presence of two distinct types of dopaminergic receptors in the neostriatum, and the involvement of other neurotransmitters (including GABA).

CONCLUSIONS

The pathophysiology of involuntary hyperkinesia in neuroleptic-treated psychiatric patients and in L-dopa-treated parkinsonian patients appears to consist of a primary dopamine deficiency (pharmacological or organic) and a secondary relative hyperactivity in the dopaminergic system (dopaminergic hypersensitivity) that may be functionally identical to a hypoactivity in the cholinergic system. The GABA system is also involved in the regulation of motor functions, and the GABA analogue baclofen influences dyskinesia in the same way as α-methyl-p-tyrosine, an inhibitor of dopamine synthesis. Baclofen, however, is not suitable for treatment of old psychiatric patients with tardive dyskinesia because of its tendency to induce sedation, muscular weakness, and confusion. Possible morpho-

logical changes of irreversible tardive dyskinesia are still unknown, but it is reasonable to assume that the neurotoxic effect of neuroleptics is related to age-dependent changes in the oral somatotopic area of the basal ganglia.

Paradoxical Response to Dopamine Agonists in Tardive Dyskinesia

BY BERNARD J. CARROLL, M.B.,B.S., PH.D., GEORGE C. CURTIS, M.D., AND EMRE KOKMEN, M.D.

The authors conducted an extensive pharmacological analysis of a patient severely affected by tardive dyskinesia. No drug treatment gave lasting clinical improvement. Several agents recently recommended for this condition, dimethyl aminoethanol, clozapine, and thioridazine, failed to modify the dyskinesia. Reserpine caused a worsening of the symptoms. A paradoxical and unexpected improvement was observed with apomorphine injections and with low-dosage oral L-dopa. These two drugs may have acted by stimulating presynaptic inhibitory dopamine receptors.

THE NEUROCHEMICAL lesion in tardive dyskinesia is not well understood, and it has not been established that all patients with the disorder have the same neurotransmitter defect(s) or will respond to the same drugs. A heterogeneity of disease mechanisms has been suggested by some authors who use the highly variable responses of patients to drug treatments as their major line of evidence (1). Consequently, there is a need for extensive use of many drugs in individual patients, both to find agents to control the abnormal movements and to provide a pharmacological profile of the disorder. Since the movements are especially variable in patients with mild forms of tardive dyskinesia, severely affected subjects are the most suitable for long-term studies. This report describes the treatment of one such patient, who took 19 different drugs over a period of 2 years. Some of the drugs were used in attempts to control the abnormal movements. After several unsuccessful clinical trials other drugs were given experimentally so that their effects on the dyskinesia could be observed and more rational treatments could then be provided.

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Drs. Carroll and Curtis are Professors of Psychiatry, Department of Psychiatry and Mental Health Research Institute, and Dr. Kokmen is Assistant Professor of Neurology, Department of Neurology, University of Michigan Medical Center, Ann Arbor, Mich. 48109.

The authors gratefully acknowledge Martin Kafka, M.D., Barry Carlton, M.D., and Randolph Nesse, M.D., residents in psychiatry, Mary Moriarty, R.N., and Catherine Doherty, R.N.; research nurses, and ward staff for their assistance in the care and study of this patient.

CASE REPORT

Ms. A was 36 years old when she was admitted to the Neuropsychiatric Institute, University of Michigan Medical Center, in February 1973. The only relevant incident in her medical history was a poorly documented episode of "subclinical poliomyelitis" at age 15. Her psychiatric illness began at age 27, when she became psychotic and was treated with ECT. The next year she became psychotic again and received neuroleptic drugs. Between the ages of 28 and 36 she was hospitalized at least 12 times and received continuous outpatient treatment in the intervals. The details of her drug treatments during this 8-year period are not known completely. There is documentation, however, that at various times she received 800 mg/day of thioridazine, 40 mg/day of trifluoperazine, and 400 mg/day of chlorpromazine, each for several months. At age 32 the first symptoms of her dyskinesia were noted in the form of frequent eye blinking and oral movements. From age 32 to age 36 she received intensive neuroleptic drug treatment, and her dyskinesia progressively worsened. For 4 months before her admission to our unit she was receiving the following drugs simultaneously: 400 mg/day of chlorpromazine, 40 mg/day of trifluoperazine, 48 mg/day of perphenazine, and 10 mg/day of benzhexol.

At the time of admission she was not psychotic. Her main psychological complaints were severe anxiety about her deteriorating marriage and distress at her abnormal movements. A careful drug history was not obtained at this time, and the patient was diagnosed as having a hysterical tic, based on the observations that her movements became more severe when she was anxious or under stress and on psychodynamic interpretations of her personal history. During her first 6 months of hospitalization she was treated in psychotherapy; haloperidol was given intermittently when her symptoms became disabling. During this period two important observations were made: 1) control of movements could be achieved temporarily with haloperidol, but they later returned even though the drug was continued; and 2) the abrupt discontinuation of haloperidol was sometimes followed by the disappearance of the movements for several days. In August 1973 a new resident and a new consultant saw the patient. Her drug history was obtained and the diagnosis of tardive dyskinesia was made.

The movement disorder involved the patient's oral-facial muscles, axial muscles (neck and trunk), and both upper and lower limbs. Frequent blinking and spontaneous blepharospasm were present; grotesque facial grimacing occurred to-

gether with rolling tongue movements and lateral movements of the mandible. These oral-facial-lingual movements were complicated by bruxism, leading to the breaking of several teeth and to occasional tongue-biting. Poor oral hygiene, drooling of saliva, and excoriation of her skin around the mouth and chin were present. When her oral movements were very severe, she was unable to eat solid food because of dysphagia. As a result of inadequate food intake and continuous dyskinetic movements she lost weight (from 50 kg to 38.6 kg) and appeared emaciated. Other features of her dyskinesia included ballistic head movements, spasm of her cervical muscles, truncal flexion, opisthotonos, abdominal rigidity, and choreoathetoid movements of her arms and legs. The overall clinical picture resembled an advanced stage of Huntington's chorea (2). When Ms. A became anxious or psychotic, the movements were exaggerated; they always disappeared during sleep. The movements could be suppressed also by competing voluntary activity; e.g., all the facial movements disappeared during forced protrusion of the tongue. Ms. A's neurological status was otherwise unremarkable except for mild rigidity of all limbs and symmetrically decreased limb reflexes. Further neurological evaluation, including skull X-ray, EEG, radioisotopic brain scan, pneumoencephalogram, and lumbar puncture yielded normal results. There was no clinical evidence to support the diagnoses of Huntington's chorea, Wilson's disease, or dystonia musculorum deformans.

DRUG TREATMENTS AND RESULTS

Group 1: Miscellaneous Sedatives

Ms. A did not improve with any of the following treatments: 90 mg/day of phenobarbital for 21 days, 400 mg/day of amylobarbital for 11 days, or 100 mg/day of diphenhydramine for 10 days. The two barbiturates produced only a decrease of anxiety symptoms without a major decrease in the dyskinetic movements. The effect of the antihistaminic drug was similar and did not suggest that central nervous system (CNS) histamine mechanisms might be implicated in the disorder. The β-adrenergic receptor blocking drug propranolol, which is effective in some extrapyramidal disorders such as familial tremor and lithium-induced tremor (3, 4), did not improve the dyskinesia when given in a dose of 160 mg/day for 8 days. The antidepressant drug desipramine, given for 11 days, did not improve or worsen the movements but did precipitate psychotic behavior. The minor tranquilizers diazepam and chlorazepate, given for 14 and 21 days, respectively, had no definite effect on the movements.

Group 2: Cholinergic and Anticholinergic Agents

Physostigmine salicylate was given intravenously in a dose of 1 mg 10 minutes after peripheral anticholinergic blockade with 2 mg of scopolamine methyl bromide intravenously. Within 10 minutes the patient developed severe rigidity and increased movements. This reaction was terminated by 2 mg of intravenous atropine sulfate.

Dimethylaminoethanol was given because of reported success in treating some patients with tardive dyskinesia (5, 6). No clear improvement in the dyskinesia was obtained with a dose of up to 1500 mg/day over 19 days. Serious peripheral cholinergic side effects occurred in the form of rhinorrhea, excessive salivation, and bronchorrhea (7).

Benztropine, an anticholinergic drug, was given in doses of 4–6 mg/day over 2 weeks. This drug caused a doubtful mild improvement in the dyskinesia together with a mild organic brain syndrome that cleared when the drug was stopped. When given in conjunction with haloperidol, benztropine did not improve the duration of control of the dyskinesia observed with haloperidol alone.

Group 3: Functional Antagonists of Dopamine

Reserpine was given because of previous reports that it and tetrabenazine were effective treatments in some patients (8, 9). At a dose of 2 mg/day for 8 days reserpine caused a marked increase of movements and severe rigidity developed along with hypotension and bradycardia.

Thioridazine at a dose of 400 mg/day for 20 days caused no improvement in the symptoms. This drug was used because of reports that tardive dyskinesia rarely occurs in patients receiving thioridazine (10).

Clozapine has been reported as dramatically effective in controlling some cases of tardive dyskinesia (11). When given at a dose of up to 1000 mg/day for 18 days, this new neuroleptic did not alter the symptoms.

Haloperidol treatment in doses of 20 mg/day produced good control of the dyskinetic symptoms on several occasions. A mild rigidity and parkinsonian facial appearance developed as the abnormal movements abated. This control persisted for 4 to 6 weeks, after which the movements returned at full intensity, despite continuation of the haloperidol. When the dose was increased to 30 or 40 mg/day, the movements were controlled again but for only 1–2 weeks before the dyskinesia reappeared. When haloperidol was then discontinued, the movements stopped rapidly within 48 hours, remained absent for 10–14 days, and then reappeared over a 2- to 3-day period. This sequence of events was documented on three separate occasions; it does not appear to have been described previously in other patients with tardive dyskinesia.

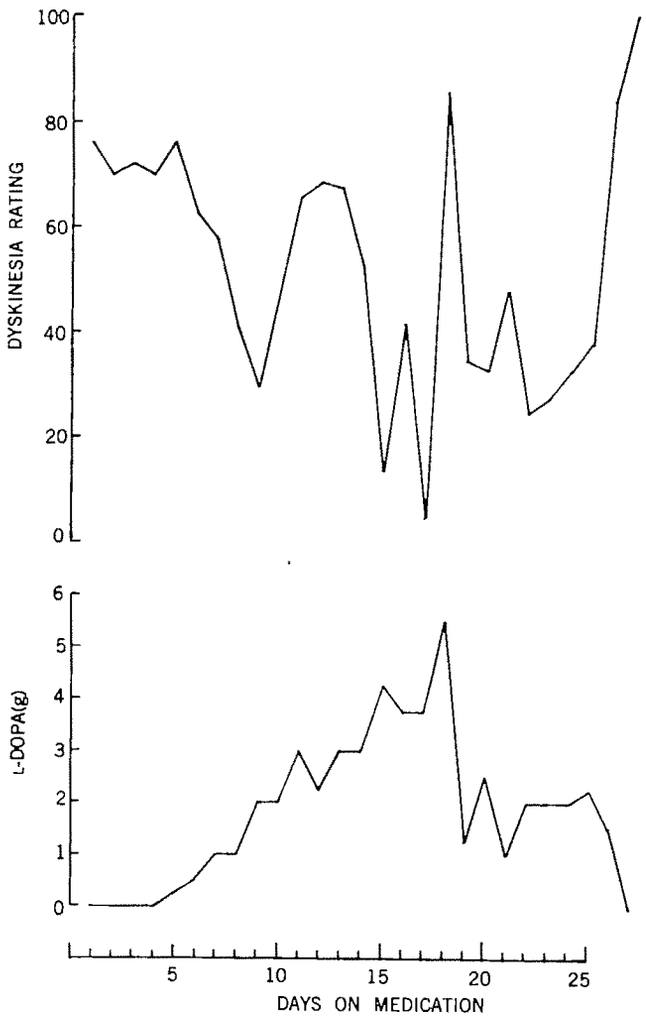
Group 4: Dopaminergic Agonists

Amantadine at 300 mg/day caused no improvement or worsening of the dyskinesia when given for 6 days.

d-Amphetamine was given once only in an oral dose of 10 mg. It caused an increase of activity and hostility together with a worsening of the dyskinesia.

L-Dopa was given in gradually increasing doses over a period of 21 days. Ratings of the dyskinesia were obtained daily by the ward staff using the Visual Analog (10-cm line) Scale of Global Severity (12). Figure 1 shows that doses between 2 and 4 g/day reduced the severity of the movements. The mean rating for 12 days when the dose was 0–2 g was 67.6 (SD=17.4) com-

FIGURE 1
Ratings of Dyskinesia Severity During Treatment with L-Dopa



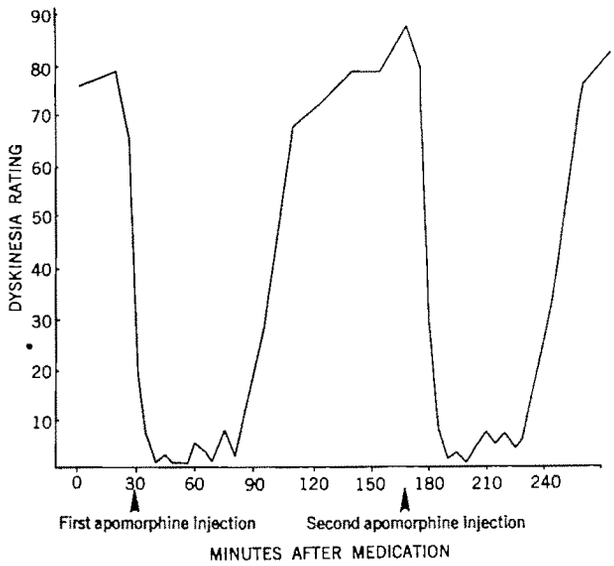


FIGURE 2
Ratings of Dyskinesia Severity After Two Injections of 4 mg of Apomorphine HCl

pared with 42.5 (SD=19.8) for 12 days at 2–4 g ($p<.01$). During this trial of L-dopa the movements worsened at a dose of 5.5 g given for 1 day, then returned to low levels at 2–3 g/day. On the final 2 days, the dose was reduced to 1.5 g and then to zero, and the dyskinesia returned at maximum intensity. During another trial with high dosage L-dopa the patient developed writhing choreiform movements and psychotic behavior.

Apomorphine, a dopamine receptor agonist, was given to determine the possible role of dopamine receptor supersensitivity in causing the dyskinesia. We expected that apomorphine would worsen the movement disorder. A dramatic and paradoxical improvement of the dyskinesia rather than a worsening followed the administration of apomorphine. In doses from 2 to 6 mg subcutaneously the drug caused a marked reduction in the movements within 10 minutes. On many occasions the movements disappeared almost completely, remained absent for up to 60 minutes, and then returned again at full intensity over a 10- to 15-minute period. Figure 2 shows this response to two injections of apomorphine. Placebo injections did not modify the movements. This effect of apomorphine was observed repeatedly. As this was the only effective treatment besides haloperidol, the patient received 2–6 mg of apomorphine subcutaneously every 2–6 hours for 2–4 weeks. Each injection was followed by suppression of the movements as shown in figure 2. After 5–7 days, however, a loss of effectiveness was noted, and responses to the drug became progressively briefer and less complete. Over these prolonged treatment periods tolerance to the emetic effect of apomorphine developed within 48 hours or less whereas the motor suppression persisted for much longer. This effect of apomorphine was antagonized by the concurrent administration of haloperidol. With prolonged apomorphine treatment the patient became dysphoric and her suicidal ideation increased.

The severe dyskinesia that occurred with high-dosage L-dopa treatment was terminated within 10 minutes by 6 mg of apomorphine subcutaneously, as described by Duby and associates (13) in parkinsonian patients.

DISCUSSION

The diagnosis of tardive dyskinesia in this patient was supported by the history of high-dosage intake of neuroleptics, by the clinical features of the movement disorder, and by the neurological evaluation, which excluded Huntington's chorea and other possible differential diagnoses. The patient's responses to drugs cannot be used at present to make the diagnosis, in view of the many negative reports associated with all of the recently proposed treatments for this disorder.

A consistent finding in this patient was the lack of

meaningful response to placebo and to nonspecific sedatives (barbiturates and benzodiazepines). Similarly, other psychotropic agents (diphenhydramine, propranolol, and desipramine) did not affect the movements.

The responses to drugs affecting acetylcholine mechanisms were investigated in view of the hypothesis that tardive dyskinesia is caused by dopamine (DA) receptor hypersensitivity, with cholinergic hypofunction in the striatum (14). In this patient, in contrast to some reports (14, 15) but in agreement with others (16, 17), physostigmine aggravated the movements and precipitated severe rigidity. Atropine reversed this acute effect of physostigmine, but benztropine given chronically did not have any definite action against the movements. That the alleged precursor of acetylcholine, dimethylaminoethanol, was ineffective is in contrast to some reports (5, 6, 18, 19) but in agreement with others (20–22). The worsening of movements and the precipitation of rigidity by reserpine was similar to the acute effect of physostigmine. It should be remembered that reserpine increases functional cholinergic activity, in addition to depleting the storage of dopamine, norepinephrine, and serotonin (23). These observations do not suggest that cholinergic hypofunction was related to the dyskinesia in this patient; conversely, they tend to indicate that cholinergic hyperfunction was present, since physostigmine and reserpine exaggerated the movements and rigidity as they do in Parkinson's disease (24, 25).

The neuroleptic drug thioridazine has strong anticholinergic activity in addition to its blockade of DA receptors (26). Clozapine, a new neuroleptic, also has strong anticholinergic properties (26). Tardive dyskinesia is said to occur rarely, if at all, with these drugs; clozapine in particular may relieve dyskinetic symptoms in some patients (10, 11, 27). Neither drug was effective in this case over periods of 2–3 weeks.

Haloperidol, on the other hand, was very effective in controlling the movements, at least for several weeks before "escape" occurred. This breakthrough phenomenon has been described previously with neuroleptics in tardive dyskinesia (28), and it has been speculated that changes in postsynaptic DA receptor sensitivity could be responsible for the effect (29). The sudden decrease in symptoms seen in this case when haloperidol was stopped cannot be explained easily, although there is no doubt about the clinical observations, which were made on three separate occasions. The definite effect of haloperidol provides good evidence for a role of activated DA receptors in the dyskinesia.

The DA precursor L-dopa had a biphasic action on the dyskinesia. At moderate doses of 2–4 g/day some definite improvement was noted. At higher doses, however, the dyskinesia was aggravated and other dyskinetic movements appeared as described in parkinsonian subjects (30). Adverse behavioral side effects of L-dopa occurred as well and were similar to those described in parkinsonism (31). This biphasic response pattern to L-dopa has been observed also in studies of animal motor activity (32).

The unexpected inhibitory effect of apomorphine on the dyskinesia suggests that DA mechanisms were involved in this case. Since apomorphine is a direct agonist of postsynaptic DA receptors (33), a worsening of the movements was anticipated. The antagonism of apomorphine by haloperidol tends to confirm the fact that apomorphine acted by stimulation of dopaminergic receptors. Recent pharmacological evidence for presynaptic receptors that inhibit synaptic DA release has been described, and it is possible that apomorphine caused its effect through activation of these presynaptic inhibitory DA receptors (34). Tolosa (35) has reported a similar inhibitory effect of apomorphine in Huntington's chorea and tardive dyskinesia. We have also observed inhibitory effects of apomorphine on the abnormal movements in patients with Huntington's chorea, spontaneous facial dyskinesia, and Gilles de la Tourette's disease (36). The antagonism of L-dopa-induced dyskinesia observed in this patient and in parkinsonian subjects (13) also supports a possible presynaptic site of action for apomorphine. In addition, the biphasic motor activity response of rats to L-dopa (32) is very similar to the biphasic effect of apomorphine (37); thus, the partial suppression of dyskinesia found in this patient with low doses of L-dopa (figure 1) could also be mediated through presynaptic inhibitory DA receptors. Gerlach and associates (17) observed a worsening of tardive dyskinesia with 1.2 g/day of L-dopa plus a peripheral decarboxylase inhibitor, but they did not report any improvement with lower doses.

SUMMARY AND CONCLUSIONS

The pharmacological studies in this patient support the concept of DA receptor activation in tardive dyskinesia (improvement with haloperidol, worsening with high doses of L-dopa, and paradoxical "presynaptic" improvement with low doses of L-dopa and with apomorphine). The mild improvement seen with benztropine and the worsening caused by physostigmine suggest that this patient could fit the "hypercholinergic hyperkinetic syndrome" described by Gerlach and associates (17). Our experience with this patient confirms the view of Granacher and associates (38) that " 'tardive dyskinesia' is a complex syndrome, and [it is] very likely that a variety of pathophysiologic mechanisms will be demonstrated. Systematic pharmacologic characterization of tardive dyskinesia in large numbers of patients remains to be done" (p. 926).

Although this patient experienced no definite benefit from any of the drugs tested, the striking temporary improvement caused by apomorphine (figure 2) suggests that other long-acting agents such as piribedil (39) may be clinically useful. The effectiveness of apomorphine that we observed was similar to that reported in two cases of dystonia musculorum defor-

mans (40) and in acute dyskinetic-dystonic reactions to haloperidol (41). Further study of agents that act presynaptically to improve tardive dyskinesia, such as apomorphine and α-methyl-*p*-tyrosine (17), is needed.

Relationship Between Age and Tricyclic Antidepressant Plasma Levels

BY ALEXANDER NIES, M.D., DONALD S. ROBINSON, M.D., MATTHEW J. FRIEDMAN, PH.D., M.D., RONALD GREEN, M.D., THOMAS B. COOPER, M.SC., CHARLES L. RAVARIS, PH.D., M.D., AND JOHN O. IVES, M.D.

Older depressed patients treated with imipramine or amitriptyline developed higher steady-state plasma levels of imipramine, desipramine, and amitriptyline. In imipramine-treated patients this finding was associated with a decreased rate of drug elimination from plasma. These findings provide at least a partial explanation for the increased susceptibility of the older patient to tricyclic antidepressant side effects and also provide a pharmacological rationale for use of lower dosages in this age group.

IT IS WELL KNOWN that clinical response to drug treatment is often altered in the elderly. Depressed geriatric patients frequently exhibit such toxic responses to tricyclic antidepressants (TCA) as postural hypotension, urinary retention, tachycardia, congestive heart failure, and organic confusional mental states. The occurrence of confusional episodes is of particular importance because it can be a confounding aspect of the tendency to misdiagnose and overdiagnose dementia in depressed geriatric patients. The fact that the elderly have greater susceptibility to TCA cardiotoxicity is usually attributed to the increased prevalence of underlying cardiac disease in the older age groups. However, it is also possible that age-related changes in drug elimination play an important role in TCA cardiotoxicity.

It has been shown that the disappearance from plasma of drugs as diverse as phenylbutazone (1), antipyrine (2, 3), penicillin (4), barbiturates (5), and propranolol (6) is slowed with age. Aside from benzodiazepines (7, 8), the effects of aging on psychotropic drug metabolism have received little attention; we have been unable to find reports of a relationship of TCA metabolism to age.

In this paper we report a study of age and TCA metabolism in patients treated with imipramine or amitriptyline. Our findings that older patients tend to have higher plasma levels and long plasma disappearance half-lives of the administered drug and its demethylated metabolite have practical implications for the treatment of depressed geriatric patients.

METHOD

Plasma TCA levels were determined in patient samples from two separate studies. The patients in the amitriptyline series were participants in a double-blind 6-week outpatient trial, and the imipramine patients were predominantly inpatients treated in a general hospital psychiatric service. Patients with serious underlying medical illness or alcoholism were excluded. The age and sex distributions of patients in the two series differed because the amitriptyline patients received treatment in a university-based depression research clinic while the imipramine patients were treated at a Veterans Administration hospital. The 35 amitriptyline patients ranged from 21 to 68 years of age, and the 23 imipramine patients ranged from 27 to

78 years. All patients participating in these studies gave informed consent according to protocols approved by the human experimentation committees of the university and the hospital.

In the amitriptyline study, following a 1-week drug-free interval amitriptyline administration was begun at a dose of 25 mg three times a day for the first 5 days and then increased to the final dosage of 50 mg three times a day. Blood was drawn at 2-week intervals and a plasma sample frozen for subsequent determination of amitriptyline and its metabolite, nortriptyline. Only patients who received 150 mg of amitriptyline a day for the final 4 weeks of the protocol were included. Inspection of the data obtained at the end of 4 and 6 weeks of treatment from these patients shows consistent amitriptyline and nortriptyline levels for each patient, indicating that patient compliance was excellent and that a steady-state level of amitriptyline and nortriptyline had been achieved.

The imipramine patients were participants in an investigation of TCA pharmacokinetics with the principal objective of assessing the relationship of imipramine elimination and desipramine disappearance half-lives to age. Most of the patients were treated with 150 mg of imipramine a day for a minimum of 21 days so that steady-state conditions were achieved (confirmed by multiple plasma drug determinations before the plasma disappearance half-life studies of imipramine and desipramine were undertaken). Previous psychotropic medications were discontinued over the first week of imipramine treatment. Chloral hydrate as a hypnotic agent and aspirin and acetominophen as analgesic agents were permitted if necessary. The plasma disappearance half-lives were computed from at least four determinations over a 48–72-hour period following discontinuance of chronic therapy.

The plasma TCA levels were determined by gas chromatography using a nitrogen detector as described by Cooper and associates (9). This method has a coefficient of variation of ±5% across the range of 4–250 ng/ml.

Imipramine elimination half-life and desipramine disappearance half-life were calculated using a standard program for fitting a logarithmic decay curve in linear form. It must be recognized that levels of desipramine in plasma obtained following the administration of imipramine are a function of metabolic generation of desipramine from imipramine and disappearance of desipramine from plasma. Therefore, the metabolic and excretory elimination of desipramine as we have studied it differs from a standard elimination half-life, and we refer to the disappearances as the imipramine *elimination* half-life and the desipramine *disappearance* half-life in recognition of the distinction.

RESULTS

Steady-state plasma levels of the two parent compounds, imipramine and amitriptyline, both showed significant positive correlations with age (see table 1). In the case of the demethylated metabolites, only the desipramine steady-state plasma levels showed a positive correlation with age; the nortriptyline steady-state levels did not. In the imipramine series the group of patients over 65 years of age (who were all nonsmokers) had significantly higher imipramine and desipramine mean steady-state levels than a group of younger nonsmoking patients (see table 2). Smokers were eliminated from this imipramine comparison because of preliminary findings that imipramine and desipramine steady-state levels may be affected by smoking (10).

The age differences in imipramine and desipramine levels occurred despite the fact that all of the younger patients were receiving 150 mg of imipramine a day but the dosage of the older group ranged from 50 to 150 mg a day (mean daily dosage of 92 mg). Dosage modification was dictated by patient tolerance to side effects (2 patients over the age of 70 experienced substantial postural hypotension, necessitating a reduction in their imipramine dosage to 50 mg a day). In the amitriptyline-treated outpatients the mean levels of only the parent compound were significantly higher in the elderly patients (see table 2).

Analysis of the plasma disappearance data for imipramine and desipramine is presented in tables 1 and 3. The disappearance half-life of desipramine is strongly correlated with patient age, while imipramine half-life correlates positively but not significantly (see table 1). It can be seen that the desipramine disappearance half-life of the over-65 age group is more than twice that of the younger group. The mean imipramine elimination half-life is only moderately longer in the elderly patients (see table 3).

Since dosage on a mg/kg body weight basis could influence plasma TCA levels, the relationship of patient weight to age was examined. No correlation of body weight with age was found for either the amitriptyline or the imipramine group. This, together with the fact that some of the elderly patients received lower imipramine dosages, excludes the possibility that the age-related differences in steady-state levels are attributable to an increased dosage (mg/kg) with age.

DISCUSSION

The cardiotoxicity of the TCAs is a current cause of concern because of the potential for lethal tachyarrhythmias and rare sudden deaths. The more common side effects attributable to their anticholinergic properties also constitute important clinical problems, especially in the elderly. Although the susceptibility of the older individual to undesirable effects of tricyclics has generally been regarded as a nonspecific intolerance of the aged to pharmacological agents, the evidence presented here would suggest that decreased biotransformation with resultant excessively higher plasma and tissue levels provides a rationale for employing lower doses of TCAs in the elderly.

Initially, TCAs were regarded as exceedingly safe drugs, with such relatively benign side effects as dry mouth, tachycardia, and occasional urinary retention in the elderly male. These compounds are concentrated in highly perfused organs (including the heart [11, 12]), and clinical reports have described cardiac arrhythmias and, rarely, sudden death in patients undergoing TCA treatment (13). The 2-hydroxy metabolites of imipramine and desipramine have been shown to produce significant cardiotoxicity in the dog at doses and tissue concentrations commonly attained in clinical use (14). It would appear that all TCAs have the capacity to produce dose-related changes in cardiac function and ECG. The dose-related ECG changes include prolongation of the PR and QRS intervals, nonspecific T wave changes, and clinical tachyarrhythmias, the most serious of which are ventricular premature contractions, heart block, and ventricular fibrillation (15, 16). The fact that a national conference was held in 1975 to examine the existing evidence on TCA cardiotoxicity, to review current FDA-approved therapeutic indications, and to revise dosage recommendations for these drugs (17) underscores the importance of establishing more precise guidelines for their use.

Only recently has it been recognized that the rate of metabolism of some psychoactive drugs decreases with advancing age. In particular, the pharmacokinetics of the benzodiazepines and barbiturates are influenced by age (5, 7, 8). This may be due primarily to a gradual decrease in specific activities of drug metabolizing enzymes in the liver as well as a possible loss of liver mass in relation to body size. Thus the older the patient, the greater the tendency to develop higher plasma and tissue levels at a given dose. Higher TCA blood levels may partially explain the increased incidence of overall side effects noted in older patients, as well as the apparently greater susceptibility of the aged to cardiac arrhythmias with TCA therapy.

In addition to these well-documented cardiovascular toxicities, adverse effects of TCAs in the CNS, with behavioral manifestations, have been described; these are often more difficult to recognize clinically. For example, Davies and associates (18) reported confusion in 13% of all patients receiving TCAs and noted that confusional episodes occurred in 35% of their patients over 40 years of age. It seems plausible that the higher incidence of this side effect among the older patients can be explained at least in part by the pharmacokinetic changes associated with aging that we observed in this study. There is a tendency among many clinicians to prematurely reject the diagnosis of depression and discontinue antidepressant treatment when organic signs appear in elderly patients. Our data suggest that downward adjustment of TCA dosage would frequently be the correct therapeutic decision in such a situation.

In the average patient, steady-state drug levels of TCAs will not be achieved for 5 to 10 days because of the prolonged elimination half-lives (averaging from 20 to 35 hours in the general patient population). Since 3 of our patients (all of whom were over 70) had desipramine disappearance half-lives greater than 80 hours, application of "5 times rule" (96% of steady-state is reached by 5 times the elimination half-life [19]) indicates that many such patients will not achieve a steady-state plasma TCA level for 2 or 3 weeks. Furthermore, at the usual therapeutic doses such patients would develop very high plasma and tissue drug levels.

Our data do not yet permit quantification and definition of toxic plasma levels for individual patients, but the results nevertheless have overall implications for dosage strategies in older patients. It seems prudent to reduce TCA dosage from that usually recommended by approximately a third to a half. Thus imipramine and amitriptyline dosage should have a maximum limit of 100 mg a day for most patients 65 years or older. For example, imipramine should be started at 25 mg daily at bedtime, with progressive increments every 4–7 days until 100 mg a day is reached or troublesome side effects intervene, whichever occurs first. As mentioned, because of the longer mean half-life in the elderly patient, steady-state levels may not be achieved for up to 2 or 3 weeks in the occasional patient (half-life more than 60 days). Therefore, more frequent and more intensive monitoring of the elderly patient is indicated during initial treatment. Because the lag period before onset of clinical antidepressant effect may include the time to reach steady-state, the standard 3-week period for completion of an adequate therapeutic trial must be extended and sometimes doubled in some depressed geriatric patients.

It is of interest that in the amitriptyline-treated patients nortriptyline plasma levels showed no age relationship (see tables 1 and 2). Although this finding will require further investigation, it is possible that clinical treatment of depressed patients over a wide age range with nortriptyline might be less complicated than with the other TCAs.

Anhedonia and Schizophrenia

BY MARTIN HARROW, PH.D., ROY R. GRINKER, SR., M.D., PHILIP S. HOLZMAN, PH.D., AND LAWRENCE KAYTON, M.D.

The authors administered semi-structured interviews to 187 psychiatric inpatients to determine the role of anhedonia in schizophrenia. The interviews were tape-recorded and then given blind ratings for anhedonia on a 7-point scale. Schizophrenic patients had significantly more anhedonia than nonschizophrenics, although many of the latter group had anhedonic tendencies. Most of the difference between the groups resulted from high anhedonia scores for chronic schizophrenics; less anhedonia was found in the acute schizophrenic patients. The data indicate that anhedonia is not necessary or unique to schizophrenia but is a prominent factor in chronic schizophrenia.

OBSERVATIONS have been made by Rado (1), Rado and Daniels (2), and Meehl (3, 4) about a marked defect in pleasure capacity, sometimes referred to as anhedonia, in schizophrenia. These views are in accord with some recent biochemical theories of schizophrenia that involve formulations about excess dopamine and the limbic system (5). Thus formulations that posit diminished experience of pleasure as a factor in the pathogenesis of schizophrenia are rooted in both clinical observation and biological inference.

In Meehl's view (3, 6), mechanisms by which anhedonia could influence the clinical picture in schizophrenia involve features such as a general weakening of positive or pleasurable emotions, an emphasis on negative components of ambivalence, and exaggerated interpersonal fears. These could lead to interpersonal distortions, cognitive slippage, and autism.

Statements about anhedonia often emphasize the lack of pleasure in interpersonal situations. Anhedonia is usually viewed as a long-term, quasi-stable, or trait-like feature present since childhood. Thus the schizophrenic is seen as an individual who from childhood on has found little reward in interpersonal situations and little reinforcement for much of the behavior for which others are routinely reinforced. The hypothesized deficiency could then be responsible for such features in the later schizophrenic as isolation from other people and withdrawal from social situations and withdrawal from reality.

It has not been established, however, that anhedonia is present in all schizophrenics. Although interpersonal aversiveness and withdrawal from social contacts are prominent in some adolescents who later become schizophrenic, there is no evidence that they are a necessary condition for schizophrenia. Indeed, a number of theorists and investigators have reported on schizophrenics who lack histories of a shy, withdrawn adolescence (7–11).

Another question concerns the specificity of anhedonia to schizophrenia. Is anhedonia also present in disturbed nonschizophrenic patients, and perhaps in normal people as well? Analysis of a sample of disturbed nonschizophrenic subjects would help to answer this and other questions.

A related issue is whether anhedonia may be characteristic of only specific types of schizophrenic pathology (e.g., of young chronic schizophrenics but not of young acute schizophrenic patients). If this is the case, anhedonia may be associated with the course of deterioration in schizophrenia for the select group of schizophrenic individuals who go downhill drastically and later become chronically ill and deteriorated (12).

The empirical literature in this area is very scant to date. We have attempted, during the course of research on schizophrenia, to investigate formulations related to anhedonia (13). A previous report from this project by Grinker (14) noted that anhedonia and depression are separate components in schizophrenia. Kayton and Koh (15), from the same project, used experimental tasks involving pleasant and unpleasant words and found evidence that schizophrenics as a group may have a decreased tendency to use features of pleasantness in their mnemonic organization.

In a series of studies, Watson (16–18) attempted to develop measures of anhedonia and to use them in an investigation of the relationship between anhedonia and physiological variables (16, 17). His results sug-

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Harrow is Director of Psychology, Michael Reese Hospital and Medical Center, 29th St. and Ellis Ave., Chicago, Ill. 60616; he is also Associate Professor, Department of Psychiatry, University of Chicago, where Dr. Grinker is Professor of Psychiatry and Dr. Holzman is Professor. Dr. Kayton is a Senior Consultant to the Illinois State Psychiatric Institute.

This research was supported in part by Alcohol, Drug Abuse, and Mental Health Administration grants MH-05519 and MH-26341 from the National Institute of Mental Health, and by Illinois Department of Mental Health grant 503.

The authors would like to thank Ms. Froma Walsh, who aided in rating the data, and Mr. Stephen Hurt, Ms. Roberta Laffey, and Ms. Beatrice Werble, who aided in data analysis.

gested that anhedonia is not a function of hyporeactivity or learning efficiency (17, 18).

Thus despite the importance of anhedonia in several modern theories of schizophrenia, there is a paucity of systematic research in this area. The present investigation is an attempt to determine whether anhedonia really does play a prominent role in schizophrenia. In particular, we will provide data on whether anhedonia is 1) a prominent characteristic of schizophrenia, 2) present in all schizophrenic patients, 3) found in nonschizophrenic patients, 4) a necessary condition in specific select types (or subdiagnoses) of schizophrenia, and 5) related to other characteristics of schizophrenia or to other clinical or personality variables.

METHOD

Sample

The subjects were 187 relatively young recently admitted psychiatric inpatients from the Michael Reese Hospital (91 males, 96 females). The sample included 128 schizophrenic and 59 nonschizophrenic patients. Five major schizophrenic groups were studied in detail: acute schizophrenics, N=19; paranoid schizophrenics, N=27; chronic schizophrenics N=58 (relatively young schizophrenics with long-standing psychopathology, slow hospital improvement, and other features of chronicity); schizo-affectives, N=11; and acute-chronic schizophrenics, N=13 (moderately well-functioning chronic schizophrenics with a current hospitalization for a sharp, acute break). The nonschizophrenic patients included depressives, N=26; individuals with severe personality disorders, N=16; and patients from varied other diagnostic groups, N=17.

The mean age of the patients was 22.43 years, with a range of 14–34 years. There was no significant age difference between the schizophrenic and nonschizophrenic patients. Almost all of the schizophrenic patients were on phenothiazine or phenothiazine-like medication (e.g., haloperidol). The patients were predominantly from Hollingshead-Redlich (19) social classes I, II, and III.

Procedure

Semi-structured interviews were conducted as early as possible during hospitalization to obtain information on anhedonia, symptom status, social and instrumental functioning, family life, and other aspects of psychopathology and personality. Since the research focused on anhedonia, the interview included a detailed investigation of "fun" and pleasurable experiences in childhood and more recently. The interviews, conducted by experienced psychiatrists who had no prior knowledge of the patients' history or diagnosis, were tape-recorded for later assessment. The 7 items on the scale were as follows:

1. Pleasure in accordance with external events.
2. Occasional but rare pleasure in accordance with external events.
3. Occasional pleasure but occurs discordant with external events.
4. Lack of humor.
5. No convincing report of ever having fun.
6. No joy, exuberance, or knowledge of shared happiness.
7. Constant sadness or boredom.

Ratings for anhedonia (and other clinical variables) were made by consensus of the research team after listening "blind" to the tape recordings. The ratings for anhedonia were made on the 7-point scale. Interrater reliability on anhedonia for two trained raters was .77, with no significant differences between their mean ratings ($t=0.30$, $df=21$, $p>.50$). The scale for anhedonia is part of the Schizophrenia Trait Inventory, a series of rating scales used to assess key clinical dimensions that may be related to schizophrenia (13, 20).

RESULTS

Differences on the Anhedonia Scale

Table 1 presents the data on the mean scores for each of the major diagnostic groups. As can be seen in the table, patients of all types showed anhedonic tendencies; 40% or more of the patients from each major diagnostic group had ratings in the range that indicates anhedonic tendencies. The combined schizophrenic group differed significantly from the nonschizophrenic group on anhedonia ($p<.01$). However, some schizophrenic subgroups showed large differences and other schizophrenic groups did not differ significantly from the nonschizophrenic group. For example, the two acute schizophrenic groups (acute schizophrenics and schizoaffectives), who in general had a better premorbid history, did not differ significantly from the nonschizophrenics. However, the chronic and paranoid schizophrenic groups showed significantly more anhedonia than the nonschizophrenic patients. The paranoid schizophrenics were primarily young, chronic paranoid schizophrenics. Thus the two groups were primarily chronic schizophrenics under the age of 30 years.

There were no significant differences on anhedonia between the two major nonschizophrenic groups (depression and personality disorder). The relatively high anhedonia scores of some nonschizophrenics suggest that anhedonia is not unique to schizophrenia; it is common among many types of psychiatrically disturbed patients.

Relationship to Other Clinical and Personality Characteristics

Table 2 presents the relationship between the patients' ratings for anhedonia and variables from the other major areas studied. These results provide fur-

ther clues as to the nature of anhedonia and its relationship to schizophrenia.

Anhedonia and depression. A critical issue is whether anhedonia is merely a concomitant of depression: our data suggest that there is a low but significant relationship between anhedonia and ratings of depression ($r=.19$, $p<.01$). This association suggests that depression accounts for a small percentage of the variance of anhedonia. In fact, no single variable we investigated accounts for a major percentage of the variance associated with anhedonia. Rather, several different types of variables show some relationship to anhedonia; these relationships are described below.

Symptom status. The clinical data (the first three items in table 2) suggest that anhedonic patients were more symptomatic ($p<.01$). The greater symptomatic distress of anhedonic patients in certain areas may have influenced the overall ratings for anhedonia slightly for these patients, although it is unlikely that the increased symptomatology alone can explain the pattern of significant relationships between anhedonia and variables in other nonclinical areas.

Chronicity and social functioning. The pattern of correlations indicates that the anhedonic patients were more chronically ill and had greater premorbid social difficulty than those without anhedonia. These data are consistent with the results reported earlier, which suggest that anhedonia is more prominent in chronic schizophrenics, even those who are relatively young. Anhedonia was related to early onset of disorder ($p<.02$) and to lack of improvement during the early period of the current hospitalization ($p<.001$). In the social area, the anhedonic patients tended to be unmarried ($p<.03$), lonely ($p<.001$), less affectionate toward others ($p<.001$), and had had few or no sexual experiences ($p<.06$). None of these variables accounted for a large percentage of the variance associated with anhedonia, but there was a consistent relationship between anhedonia and variables associated with chronicity and social isolation.

Prehospital competence. Another area that had a low but definite relationship to anhedonia is prehospital competence. The anhedonic patients tended to have had poorer functioning and less coping capacity before hospitalization than nonanhedonic patients. They had poorer overall organization ($p<.001$) and more identity problems ($p<.006$). Their adjustment prior to the overt onset of their disorder was poorer ($p<.05$), as were their premorbid school and work performance ($p<.002$). These variables round out a picture of less competence in the anhedonic patients.

DISCUSSION

Anhedonia in Schizophrenic and Nonschizophrenic Disorders

In previous reports based on smaller samples and with less systematic samples of control patients other investigators and members of our group have noted evidence of anhedonia in many schizophrenic patients. The results of this study, which show high levels of anhedonia in certain groups of schizophrenics, are only partly in accord with these reports. Our evidence indicates that 1) anhedonia is not characteristic of all types of schizophrenics, 2) anhedonia is also found in many disturbed nonschizophrenics, and 3) anhedonic characteristics seem to be present in mild to moderate and at times moderate to severe degrees in a variety of patients. These results raise questions about generalizations that have been made in the past concerning the relationship between anhedonia and schizophrenia.

Anhedonia may be a concomitant of other features (e.g., a certain type of chronic depressive outlook on life) that accompany a variety of different types of dis-

turbances. The data suggest that it is not present in all psychopathological conditions.

The results do not support Meehl's hypothesis that anhedonia is an inevitable feature of schizophrenia. However, the role of anhedonia in schizophrenia still must be taken into account, since it was more frequent in the schizophrenic group as a whole and there was a strong trend for specific schizophrenic subgroups to show anhedonia. These results suggest that anhedonia may play some part in the overall picture of schizophrenia and may be a key factor in chronic schizophrenia. Hence a modified and more modest view of the Meehl hypothesis of anhedonia centered around certain specific subgroups of schizophrenics is still feasible.

Anhedonia in Chronic Schizophrenia

The prominence of anhedonia in chronic schizophrenic patients can be viewed in several ways. One possibility is that anhedonia is a consequence of chronicity or of deterioration; thus schizophrenics who have become "chronic" begin to appear pleasureless during the course of their disorder. However, the evidence suggests that while chronicity could play some role, it is not enough to account for all of the relationship between anhedonia and chronic schizophrenia. Many patients' histories indicate the presence of anhedonia in childhood, before the onset of overt schizophrenic symptoms.

A second possibility is that anhedonia is a condition of dementia praecox, i.e., "true" or chronic schizophrenia. Anhedonia was extremely common in our more chronic schizophrenic subjects. In addition, anhedonia was more frequent in schizophrenics who were unmarried and had poorer premorbid social functioning and in those who had poorer premorbid work and school performance. These relationships are consistent with a view (still undocumented) that anhedonia is a significant aspect of the subgroup of schizophrenia characterized by poor premorbid functioning and that the schizophrenics without anhedonic tendencies who have good premorbid characteristics are cases of schizophreniform psychosis.

A third possibility, which is consonant with our data, is that anhedonia is important at an early age and is one of the factors that influence the course of the disorder toward chronicity. This third formulation suggests that anhedonia is not a major etiological factor in schizophrenia; however, once a person becomes psychotic, the presence of anhedonia (and other associated factors) becomes important in determining the chronicity of the illness. Thus anhedonia could have a negative influence on prognosis or it could be a concomitant of other factors that negatively influence the course of the disorder.

Behavioral Toxicity and Equivocal Suicide Associated with Chloroquine and Its Derivatives

BY MICHAEL I. GOOD, M.D., AND RICHARD I. SHADER, M.D.

Although the antimalarial agents chloroquine, hydroxychloroquine, and amodiaquine are widely used to treat a variety of medical conditions, their behavioral toxicity and lethality are not generally recognized. Therapeutic doses sometimes cause psychosis, delirium, personality change, and depression. Since moderately low overdoses of chloroquine can result in rapid death, such behavioral effects could lead to accidental or state-dependent overdosage and death.

THE INCREASING role of the psychiatrist in the general hospital (1) has paralleled an expanding awareness of medication-induced behavioral changes among nonpsychiatric patients and an increasing number of drug-related hospital admissions (2). It is now widely known that certain drugs, such as steroids and digitalis, cause psychiatric symptoms.

The behavioral toxicity and the lethality of chloroquine have received relatively little attention in the American medical and psychiatric literature. It is one of a small number of medications that can not only significantly alter mental status but also cause death from moderate overdoses. This drug thus has particular significance for the psychiatrist, internist, toxicologist, and suicidologist. Chloroquine and its derivatives are also of special interest at the present time because of their widespread use in rheumatology and the upswing in their use as antimalarials as Americans travel more readily to countries in which malaria is endemic.

BEHAVIORAL TOXICITY

Chloroquine use is associated with psychosis, personality change, depression, and delirium. At least 10 cases of chloroquine psychosis (3–10) and 1 case of "personality change" (11) have been reported in the English-language literature since 1958. In a study by Mrňa and associates (12), 6 of 21 patients receiving chloroquine (28%) developed neurotic-like disturbances (4 neurasthenic and 2 hysteriform). Psychotic symptoms reportedly have developed after total doses of 2.0 to 6.0 g of chloroquine sulfate or phosphate and after an elapsed time from initial dose ranging from 2 to 40 days (usually 4 days). These cases included patients without a history of psychiatric disturbance. The psychological changes reversed upon drug discontinuation, usually within about a week (9), but not for 8 weeks in one inconclusive case (6), and with recurrence of symptoms even after discontinuation in another case (10). Reinstitution of therapy usually failed to reproduce significant symptoms (3), but not in all cases (10). The psychosis is probably toxic and caused by the drug itself rather than by malarial infection or concurrent factors (13). The possible role of premorbid mental susceptibility or idiosyncrasy has been considered but remains undetermined (3, 5, 9). Age and sex appear to offer no predisposition. Significantly, patients had some insight into their condition in the early stages (8).

It should be noted that secondary psychiatric symptoms may mask early delirium due to chloroquine and give the false impression of a purely psychogenic illness (14). For example, Mustakallio and associates (5) reported that a 40-year-old forester treated with chloroquine for atopic dermatitis became preoccupied with a panicky fear of "going mad" and could no longer control his intentional behavior, which became characterized by various irrational and compulsive impulses, noisiness, and aggressiveness. The patient described by Kabir (9) was also irritable and abusive. Brookes's patient (8) was depressed and confused but was aware that he was acting abnormally.

Depression has been reported in relation to treatment with chloroquine as well as its congeners, hydroxychloroquine and amodiaquine. Drew (15), for example, described his experience with a variety of side effects of antimalarials used in the extended treatment of rheumatoid diseases in 65 patients (56 women and 9 men) ranging in age from 19 to 71 years (average, 47 years). Sixty-two percent of the whole group developed psychological symptoms. Of the 21 patients on chloroquine sulfate, 43% developed such symptoms, as did 29% of the 28 patients on hydroxychloroquine sulfate and 72% of the 25 patients on amodiaquine. (Some patients received more than one drug course.) Daily doses of the drugs were comparable, averaging about 150 to 200 mg. The duration of treatment averaged about 1 to 1½ years and ranged from about 2

Dr. Good is Director of Children's Services, West-Ros-Park Mental Health Center, 1842 Centre St., West Roxbury, Mass. 02132, and Assistant Clinical Professor of Psychiatry, Tufts University School of Medicine, Boston, Mass. Dr. Shader is Associate Professor of Psychiatry, Harvard Medical School, and Director of Training and Education, Massachusetts Mental Health Center, Boston, Mass.

months or less to 3 or 4 years. Drew noted that his series was largely composed of women of menopausal age and that some symptoms could thus be related to factors other than a direct toxic effect. Nevertheless, he observed that feelings of tiredness and depression were the earliest and most common toxic symptoms. Depression ranged from mild to severe and required treatment when the drug was continued. Several patients required antidepressant drugs. Three patients consulted psychiatrists; 1 received ECT. Other symptoms observed were claustrophobia, inferiority feelings, loss of sleep from noxious dreams, suspiciousness, and loss of affection. All these aberrations rapidly disappeared with drug withdrawal. Drew made no mention of suicidal ideation, cognitive impairment, or other signs of organic brain syndrome.

A previously published case (10) reported the occurrence of suicidal thoughts and an acute panic reaction with ego disorganization in a 15-year-old boy who was receiving chloroquine phosphate for a benign skin disorder. When the drug was begun he became drowsy and unable to think clearly. On the 11th day of treatment with a total of 4.25 g of chloroquine, the drug was discontinued because the patient developed depression with suicidal thoughts, restlessness, insomnia, and anorexia. His mood subsequently improved, and chloroquine was restarted on the 18th day, but severe depression recurred, and the drug was again stopped on the 28th day. On the 33rd day he was seen as a psychiatric emergency; he had uncontrolled outbursts of crying and self-accusation, ego-alien thoughts, and loose associations. Orientation and judgment reportedly were intact. There were some exacerbations of symptoms even in the month after the chloroquine was finally discontinued, although after 40 days the patient was improved.

The psychiatric literature to our knowledge includes only one report, by Rockwell (16), of either the behavioral toxicity or the lethality of chloroquine and derivatives. Rockwell included suicide as a possible psychiatric complication of chloroquine use and cited acute psychosis and delirium and their early manifestations as signs of its behavioral toxicity. However, he did not mention depression or other less acute or less dramatic mental changes or suggest any possible relation between behavioral toxicity and suicidal behavior. Reports of chloroquine-related depression, toxic psychosis or delirium, and irrational compulsive impulses raise the possibility of a relationship between chloroquine toxicity and lethal chloroquine ingestion.

Of related interest is the Amok syndrome sometimes seen in males in Southeast Asia, Indonesia, Papua New Guinea, the Phillipines, Africa, and other tropical areas. Amok is a sudden, often psychotic disturbance that is associated with homicides and suicides and is apparently culturally bound. Although its etiology is unknown, it is interesting that infections such as malaria and "toxic" processes have been hypothesized as possible physical causes (17). Antimalarials could play a role in this tropical syndrome.

Reports of the effects of chloroquine on the EEG vary (12, 18–20). In general it appears that chloroquine acts as a cerebrocortical stimulant that increases EEG frequencies, but it also decreases voltage and may occasionally cause seizures.

LETHALITY

It is ironic that chloroquine is more lethal than its forerunner quinacrine, which is generally considered to be more toxic (21). Chloroquine generally causes poisoning within hours; toxic symptoms or death have reportedly occurred as early as 30 to 45 minutes after oral overdoses (22–24). Such deaths usually have been considered secondary to hypersensitivity, with the drug itself described as relatively safe. In fact, however, the margin of safety is narrow: lethal doses reported for chloroquine sulfate are as low as 1.0 to 1.5 g, usually less than 8 or 10 g, and most frequently 2 to 4 g (25–30). Survival is rare without prompt emergency treatment following overdosage (31–33). Despite reports of the lethality of chloroquine, most medical and toxicological textbooks and references do not mention this fact (34). Hydroxychloroquine, which was introduced in 1955 and is considered less toxic than chloroquine, can also cause fatal poisoning (35, 36).

REVIEW OF REPORTED OVERDOSES

A review of the literature on chloroquine and hydroxychloroquine ingestions yielded reports of at least 134 overdoses, more than three-quarters of which led to death (22–59). (In some instances in the remaining cases the outcome was not mentioned.) Two lethal cases involved hydroxychloroquine (35, 36). Among adult cases in which the sex of the deceased was specified there was an approximately equal number of fatalities among men and women.

Fifteen cases were apparently unintentional overdoses in children (22, 25, 26, 37, 41–43), and there is at least 1 report of a clearly accidental overdose in an adult (46). Eighteen cases, 1 of which involved hydroxychloroquine (35), were apparent abortion attempts (27, 29, 35, 45, 49). Three additional deaths resulted from normal therapeutic use (29).

Many of the remaining cases are more difficult to classify and raise questions. Some of the ingestions considered to be suicides or suicide attempts seem equivocal in retrospect (24, 25, 47, 48, 50, 52). In fact, investigations of the possibility of murder were initiated in some fatal cases but homicide was eventually ruled out. The number of early reports of deaths from chloroquine ingestions suggests the need for a concerted pursuit of an additional clue to explain the lethal outcomes. In all cases reported, however, the overdoses were ultimately described or labeled as definite suicides or parasuicides, clear accidents, or abortion attempts, or they were simply not considered fur-

ther. For example, Kiel (39) reported 13 cases, 6 of which were acknowledged to be questionable suicides. Yet, as if to resolve the mystery, he then concluded that suicide was probable in such cases without specifying other possible explanations.

It is known that therapeutic doses of certain medications can alter or impair consciousness in some patients. Aspects of consciousness susceptible to toxic effects include perception, attention, information processing, memory, and affective state, any of which in turn can influence motivation and behavior. Consequences of behaviors performed during a toxic state may be quite contrary to what an individual would have intended if free from toxic effects. This concept has been used to account for certain cases of drug overdosage in which self-destructiveness either probably was not intended at the time of overdosage or, if intended, probably would not have been carried out under drug-free conditions (60).

We have been unable to locate in the psychiatric literature any reports of apparent suicide by chloroquine ingestion, and the cases reviewed above do not report employing a "psychological autopsy" (61) or similar procedure in reviewing the deaths. Nor is there any mention, with one exception (31), of psychiatric evaluation of patients who survived chloroquine ingestions. Wilkey (25) observed that chloroquine poisoning may be unsuspected until the toxicologist's report is seen and concluded that accidental therapeutic overdosage may be underdiagnosed in some areas. The possible facilitating role of behavioral toxicity in chloroquine deaths in which the mode of death is unclear but accidental or suicidal ingestion is likely needs further evaluation.

We recommend that the mental status of patients be evaluated before administration of chloroquine and related drugs and periodically during their use and that there be more detailed investigation of the nature and cause of antimalarial overdosage.

Social Adjustment Profiles of Female Drivers Involved in Fatal and Nonfatal Accidents

BY JOHN W. SHAFFER, PH.D., CHESTER W. SCHMIDT, JR., M.D., HOWARD I. ZLOTOWITZ, AND RUSSELL S. FISHER, M.D.

Previous research by the authors has shown that male drivers involved in fatal and nonfatal accidents can be differentiated from the general population on the basis of background, behavior, and social adjustment. The results of the present study suggest that female drivers involved in serious crashes do not differ from the overall female driving population.

ON THE BASIS of a considerable amount of research conducted over the past 2 decades, it now seems fairly well established that certain personal and behavioral characteristics of drivers are significantly associated with traffic violations, injuries, and fatalities (1, 2). However, what may not be well known is that most of the research relating driver characteristics to traffic accidents and violations deals almost exclusively with men. In large measure this is because men are much more frequently involved in traffic accidents, especially those involving driver fatalities. (According to data from the Maryland State Police, in 1975, 85% or 304 of the 357 drivers killed in motor vehicle accidents in the state of Maryland were men.)

For the past 9 years we have been conducting in-depth studies of fatal and nonfatal traffic accidents. To date, several articles and reports derived from this continuing investigation have been published (3–5); however, most of them dealt exclusively with male drivers. One of the most prominent and consistent findings is that fatally injured, legally culpable male drivers significantly differ from a comparable normative sample on a variety of behavioral traits that may be subsumed under the general heading of social obstreperousness. The prior existence and prominence of such traits is supported by the subjects' driving records, which indicate a high incidence of convictions for moving violations, and by excessive blood alcohol levels at autopsy in many cases.

Dr. Shaffer is Associate Professor of Medical Psychology, Johns Hopkins University School of Medicine, Baltimore, Md.; Dr. Schmidt is Chief, Department of Psychiatry, Baltimore City Hospitals; Mr. Zlotowitz is Systems Analyst, Maryland Medical-Legal Foundation, Inc.; and Dr. Fisher is Chief Medical Examiner, State of Maryland, and Clinical Professor of Forensic Pathology, University of Maryland School of Medicine. Address reprint requests to Dr. Shaffer, 406 Crosby Rd., Baltimore, Md. 21228.

This work was supported by contract HS-198-3-770 from the Department of Transportation, National Highway Traffic Safety Administration, administered by the Maryland Medical-Legal Foundation, Inc., Russell S. Fisher, M.D., Principal Investigator, and by an institutional research grant from the Baltimore City Hospitals, Chester W. Schmidt, Jr., M.D., Principal Investigator.

That the above relationships currently hold true among culpable male drivers can scarcely be doubted. The question remains, however, as to the generalizability of such findings with respect to female drivers. The meager evidence available on this issue is equivocal and for the most part limited to studies of the incidence of past driving offenses rather than the occurrence of fatal or nonfatal accidents (1, 2). This article represents a preliminary effort to shed light on this important issue.

METHOD

Sample

All of the fatal cases involving female drivers were drawn from the population of driver fatalities in the Baltimore metropolitan area between October 1968 and October 1974. With relatively few exceptions, the 30 fatalities reported herein represent a virtual census of their type occurring within the temporal and geographical constraints stated. A requirement for inclusion in the study was the death of the driver within 24 hours of the accident.

Because of the relatively small number of cases available for study, we felt that the research goals could be furthered by investigating 24 potentially fatal accidents that resulted in only slight injuries to the female drivers.

Procedure

After referral of an eligible case from the Chief Medical Examiner's office, we conducted a multidisciplinary investigation into the circumstances surrounding the accident. This included physical autopsies of the victims, including determination of blood alcohol levels; inspection of the accident site and the vehicle(s) involved; inspection of police reports and Motor Vehicle Administration records; and, whenever possible, comprehensive psychological interviews (both structured and unstructured) with relatives and friends of the victim.

This article deals primarily with the results of the Katz Adjustment Scales (R-form) (KAS) (6). This instrument consists of 205 scaled items that permit a retrospective, quantitative description, by an informant, of the subject's individual and social behavior. The KAS provides scores on 18 cluster-analytically derived dimensions pertaining to psychiatric symptoms as well as social activities. The recent availability of normative data (7) obtained from a systematic random sample of male and female residents of a nearby Maryland county has greatly increased this instrument's general utility.

In each case the KAS was completed by an informant (usually a spouse, parent, sibling, or other close relative) who had been in close contact with the subject during the weeks and months prior to her fatal, or potentially fatal, accident. In accordance with standard instructions, informants were asked to describe the subject as she had appeared to them during the few weeks immediately before the accident in question.

Data Analysis

All completed KAS forms were scored by computer. Raw scores on each scale were subsequently transformed to standardized T scores based on the normative data for females supplied by Hogarty and Katz (7). These T scores have a mean of 50 and a standard deviation of 10 in the normative group, and the transformation affords ready intergroup as well as intragroup comparisons.

RESULTS

Demographic and Situational Variables

Although the two groups of female drivers (surviving and fatally injured) differed significantly on only one of the demographic or background variables studied, we are reluctant to combine the data in several instances since the small samples involved preclude sensitive tests of significance.

The mean age of the dead drivers was 41.3 years ±16.9; that of the surviving drivers was 36.0 years ±17.1. The groups had a similar racial composition, with 28% being black and the rest white. Thirty-seven percent of the fatally injured drivers were either separated or divorced, compared with only 4% of the surviving drivers ($p<.05$). According to the Hollingshead and Redlich two-factor index (8), social class distribution was similar for both groups; 14% were in class V, 34% in class IV, and 52% in class III or above.

Because the previous driving records of the two groups were remarkably similar, we will present data for the sample as a whole. Unlike the driving records of the fatally injured male drivers (5), the records of the female drivers were relatively unblemished. Only 22% had had one or more previous convictions for speeding, and only 9% had had two or more. Only 4% had had their licenses suspended, and only 2% had had their licenses revoked. None of the subjects had been convicted of drunken driving, and only 24% had had one or more convictions for a moving violation of some other type. According to Motor Vehicle Administration records, 17% had had previous accidents; in this respect, the female drivers resembled the fatally injured male drivers.

Turning now to circumstances surrounding the accident itself, 38% of the surviving drivers but only 3% of the fatally injured drivers had been wearing seat belts (with or without upper body restraint) ($p<.01$). Seventy-one percent of the surviving drivers but only 43% of the fatally injured drivers were involved in single-car accidents; this difference is not statistically significant. In addition, nearly 92% of the surviving drivers and 80% of the fatally injured drivers were legally at fault.

Blood alcohol levels were determined at autopsy for the 30 fatally injured drivers. Unlike the male driver fatalities previously reported, 67% of these female

TABLE 1

Mean T Scores on the Katz Adjustment Scales (R-form) for Two Samples of Female Drivers Involved in Fatal and Nonfatal Accidents

Katz Adjustment Scales	Fatal Accidents (N=16)	Nonfatal Accidents (N=18)	Combined Sample (N=34)
Belligerence	58.0	53.1	55.4
Verbal Expansiveness	51.6	47.0	49.2
Negativism	50.4	49.3	49.8
Helplessness	49.0	49.8	49.4
Suspiciousness	49.8	48.1	48.9
Anxiety	49.9	46.7*	48.2
Withdrawal and Retardation	47.3	49.1	48.3
General Psychopathology	51.9	46.4	49.0
Nervousness	51.5	48.3	49.8
Confusion	50.7	47.2**	48.8
Bizarreness	50.1	48.8	49.4
Hyperactivity	50.3	45.2*	47.6
Stability	53.9**	53.9**	53.9*
Level of Performance of Socially Expected Activities	57.4*	57.1**	57.3*
Level of Expectations for Performance of Social Activities	55.6**	56.6*	56.2*
Level of Free-Time Activities	48.8	46.3	47.5
Dissatisfaction with Free-Time Activities	46.9	52.2	49.7
Dissatisfaction with Performance of Socially Expected Activities	45.8**	49.0	47.5

*Significantly different from normative mean of 50 ($p<.01$).
**Significantly different from normative mean of 50 ($p<.05$).

drivers had no measurable blood alcohol levels, and an additional 10% had levels less than .10 mg/100 ml, the point at which driving ability is definitely impaired (9). Thus the incidence of alcohol involvement appears to be only about half that found in a comparable series of male driver fatalities (5).

For the 24 surviving drivers, accurate determination of blood alcohol levels was much more problematical. However, on the basis of confidential interview data and police notes, it appears that no more than 17% of these accidents could be described as alcohol related.

Katz Adjustment Scales Profiles

KAS profile data were available for only 16 fatally injured drivers and 18 surviving ones; in the rest of the cases there was no reliable or sufficiently cooperative informant. However, subsequent correlational analyses suggested that the persons for whom KAS profiles were available were generally representative of their respective total groups.

Table 1 presents the mean T scores on each of the 18 KAS scales for each group separately and for both groups combined. Combination of the data in this fashion may be considered permissible on two grounds: 1) the nonfatal accidents had the *potential* for fatal injury, and 2) there were no statistically significant differences between the two groups on any of the 18 KAS scales.

Perhaps the most important feature of the summary statistics in table 1 is their essential *lack of deviancy* from the normative population in any undesirable or pathological sense. In contrast with comparable data on male drivers (5), which indicated significantly elevated mean scores on several quasi-undesirable characteristics, the present data on female drivers suggest that any deviancy present is of a positive sort, i.e., the female drivers appear, on the average, to be more emotionally stable and socially competent than the female comparison group (7). Unlike the male drivers, the present sample did not have elevated scores on the scales measuring verbal expansiveness, negativism, hyperactivity, and general psychopathology.

COMMENT

As Nunnally (10) has aptly noted, one of the truisms in psychological assessment is that men and women tend to differ in almost all respects. Despite this fact, many researchers persist in combining data on men and women. It would be interesting to know how many potentially significant findings have been overlooked through the mutual cancellation of divergent and sex-specific trends.

The more than adequate level of social adjustment that appears to characterize the female drivers as a group is in striking contrast to the somewhat undesirable traits of their typical male counterparts. While both sets of findings could be dismissed as mere artifacts of the assessment procedure or as biases associated with available norms, the implications of the profile differences are amply supported by equally striking differences in past driving records. The women's records were relatively unblemished; the men's records were not. Moreover, alcohol involvement, that tired explanation for automobile crashes that really does not explain anything (11), was much more common among the male drivers.

The implication of the present findings is that female drivers involved in fatal or other serious accidents are not particularly different from other female drivers, at least not in terms of any of the undesirable traits that seem to distinguish their male counterparts. Viewed in the aggregate, the available data on the female drivers provide no suggestion of social maladjustment, dangerous lifestyles, or poor driving habits. Indeed, there is slight evidence to the contrary. Faced with such unexpected findings, we can only conclude that the women in our samples were just unlucky—they happened to be at the wrong place at the wrong time. If such a tentative conclusion is borne out by further investigation, it could have important implications for theories of accident causation.

Platelet Monoamine Oxidase in Chronic Schizophrenia

BY WADE H. BERRETTINI, M.D., WOLFGANG H. VOGEL, PH.D., AND ROY CLOUSE, M.D.

The possibility that altered central nervous system monoamine function exists in the major psychoses has led to the investigation of platelet monoamine oxidase (MAO); it is hoped that peripheral MAO levels reflect brain levels. There appears to be mounting evidence that platelet MAO activity in chronic schizophrenics is decreased compared with that of normal individuals (1, 2). Other investigators have shown that there is no significant difference in MAO activity in acute schizophrenics (3, 4). This has led to the hypothesis that there are unknown, uncontrolled factors which are responsible for the differences seen in chronic schizophrenia; others claim that the difference may be a genetic marker for the disease (2).

Since most studies have used only one substrate concentration in their assays, which does not allow for kinetic interpretation of the enzyme, we studied MAO activity in platelets of chronic schizophrenics at various substrate concentrations to obtain information on maximum velocity (V_{max}) and K_m. These two constants provide additional information concerning enzyme differences.

Method

Subjects. Twelve chronic schizophrenic inpatients were selected for this study, 5 from Thomas Jefferson University Hospital and 7 from Albert Einstein-Southern Division Hospital. We selected patients who had been hospitalized for 2–5 weeks so that we would have an accurate record of drug intake. It was not considered necessary for patients to be drug free because the major antipsychotic drugs, such as phenothiazines and butyrophenones, do not alter MAO activity (1, 5).

The 12 patients (3 women and 9 men) had an average age of 32.1 years (range, 18–45). The average time since the initial diagnosis of schizophrenia was 8.4 years (range, 2–18). In all cases the clinical diagnosis of two psychiatrists was accepted. On admission, all patients were considered to have flat or inappropriate affect, delusions, and looseness of associations; 9 admitted to auditory hallucinations and 4 to suicidal/homicidal ideation. No patient had a history of depressive psychosis or use of antidepressant medication, and there was no evidence of iron deficiency anemia. Informed consent was obtained from all subjects.

Age- and sex-matched controls were selected from laboratory personnel and from the staff of both psychiatric inpatient units. These subjects had no personal or family psychiatric history and were not taking drugs.

Enzyme preparation. Approximately 10 cc of venous blood was drawn from a peripheral vein directly into two ethylenediaminetetraacetic acid (EDTA) treated vacutainer tubes. Platelets were isolated as follows. Whole blood was centrifuged for 30 minutes at 275 *g*. The platelet-rich plasma was separated and spun for 20 minutes at 1300 *g*. The resultant platelet plug was washed 2 times with 1 ml of Ringer's solution, suspended in 0.9 ml of Ringer's solution, and homogenized with 50 up-and-down strokes in a glass-Teflon homogenizer. These steps were carried out at 5° C. No more than 2 hours elapsed between venipuncture and platelet assay. Protein content of the homogenate was estimated by Miller's modification (6) of Lowry's method.

Assay. Using the method of Wurtman and Ax-

elrod (7), 50 μl of the platelet homogenate were added to test tubes containing 200 μl of Sorensen's phosphate buffer (0.05 M, pH=7.4), with final concentrations of [2-^{14}C] tryptamine (New England Nuclear Corp., Boston, Mass.; specific activity, 48.5 mCi/mmol) ranging from 2.7 × 10^{-5}M to 1.3 × 10^{-4} M. Reactions occurred at 37° C and were stopped at 30 minutes by the addition of 0.5 ml of 2 N HCl. Metabolites were extracted into 6 ml of toluene and measured in 10 ml of a standard fluor in a Packard Model 3375 scintillation counter.

Results

As table 1 shows, both the mean K_m and the mean V_{max} of platelet MAO were significantly lower for chronic schizophrenics than for normal control subjects. Chronicity or severity of symptoms was not correlated with K_m or V_{max}.

Discussion

The finding of a lower V_{max} in patients with chronic schizophrenia is consistent with the reports of decreased platelet MAO activity in this disease (1, 2). The failure to find differences in studies of platelet MAO in acute schizophrenia is interesting given Rosenthal's finding of no increased incidence of schizophrenia in the families of acute schizophrenics (8). This is in direct contrast to the well-documented familial aspect of chronic schizophrenia. The difference seen in the V_{max} may be the result of a genetically determined variation in MAO.

This is, as far as we are able to determine, the first report comparing the platelet MAO K_m value in chronic schizophrenics to that in a control population. It is interesting to note that there appears to be a bimodal distribution of K_m values among the control population, while no such distribution was noted in the chronic schizophrenic patients, all of whom had a lower K_m value. These data are consistent with the hypothesis that there is a commonly occurring genetic variation of platelet MAO which is associated with chronic schizophrenia. Chronic schizophrenia may be associated with what Johnston calls an abnormal "type B" MAO (9). Evidence for this hypothesis comes from studies of platelet MAO and from analysis of MAO metabolites in the cerebrospinal fluid of chronic schizophrenics (10). Whether this association is related to schizophrenia in terms of pathogenesis must be determined in future investigations.

The data we have presented seem to indicate the existence of two distinct types of MAO—an MAO with a higher affinity for tryptamine and a generally lower maximum velocity and an MAO with a lower affinity for tryptamine and a higher maximum velocity. The first type occurs consistently in chronic schizophrenics and in one segment of the control population. One can speculate that it is this change in MAO which predisposes to chronic schizophrenia.

Deanol in Tardive Dyskinesia

BY KENNETH L. DAVIS, M.D., PHILIP A. BERGER, M.D., AND LEO E. HOLLISTER, M.D.

Tardive dyskinesia is a syndrome of involuntary movements of the mouth and extremities that follows treatment with antipsychotic drugs. Pharmacologically induced supersensitivity of dopamine receptors may disturb the usual balance between dopamine and acetylcholine in the striatum, resulting in predominance of dopamine. Attempts to treat tardive dyskinesia by reducing dopaminergic activity have not been especially fruitful. Increasing cholinergic activity by administration of physostigmine produces a transient but definite improvement (1). In order to exploit this phenomenon in a clinically useful way, dimethylaminoethanol (deanol) was proposed as a precursor for acetylcholine, and several studies have reported beneficial effects from such treatment, usually in doses not exceeding 1500 mg/day (2–5).

We treated four patients suffering from tardive dyskinesia with deanol. Three patients had a stable buccolingual masticatory movement for 6 months to 1 year. These patients received up to 1600–2000 mg/day for 21 to 56 days, with no improvement in the frequency or intensity of their movements as compared with predrug movement frequency. Patients placed on 14 days of placebo following deanol had a movement frequency indistinguishable from the frequency during deanol administration. One patient with tardive dyskinesia of only 2 weeks' duration experienced a complete disappearance of all movements shortly after beginning treatment with deanol in a dose of 1 g/day. This remission persisted throughout a 21-day placebo period and the syndrome has not recurred to date, which indicates that the patient had a spontaneously reversible withdrawal dyskinesia. Our experience differs from the earlier more positive reports and indicates that selection of patients is critical, since cases of reversible dyskinesia might improve spontaneously. Deanol in the doses we used is not effective for well-established cases of tardive dyskinesia.

Deanol is not converted to choline in the brain, but must first be converted to choline in the liver, where it ultimately becomes phosphatidylcholine, a major constituent of brain lipids (6). Incorporated choline can be freed in the brain by hydrolysis of phosphatidylcholine, but the extent of this source of choline for synthesis of acetylcholine is undetermined (7). Choline chloride, theoretically more available for acetylcholine synthesis in the brain, has been more effective in our experience (8). If deanol were to be made equally available as a precursor, it would have to be given in much larger doses—probably 8–20 g/day. One of the patients who failed to improve when given 2 g/day of deanol for 51 days improved when placed on 20 g/day of choline chloride. Further studies will be required to compare deanol with choline as a truly effective precursor for acetylcholine in the brain.

Response to Lithium in a Case of L-Dopa-Induced Psychosis

BY WILLIAM BRADEN, M.D.

There have been reports of psychoses induced by L-dopa in the treatment of Parkinson's disease (1). L-dopa, a precursor of dopamine, is thought to act by increasing dopamine synthesis in the central nervous system. Psychoses induced by L-dopa are thus of some theoretical interest because alterations of dopamine metabolism have been implicated in naturally occurring manic (2) and schizophrenic (3) psychoses. I would like to report a case of L-dopa-induced psychosis that apparently responded to lithium carbonate treatment.

Case Report

Mr. A, a 64-year-old retired man with Parkinson's disease, was admitted to a psychiatric hospital in December 1975 because of increasing hostility and suspiciousness. He had no history of psychiatric treatment, but the family had noted occasional suspiciousness toward business associates. Mr. A was described as a heavy drinker and a hard worker until the onset of Parkinson's disease in 1972. At that time he stopped drinking, had to leave his job, and felt bitter about the loss of his independence. He was treated with up to 8 g/day of L-dopa, with good remission of parkinsonian symptoms. However, he gradually became delusional, refusing on one occasion to start his car because, he said, "the Mafia had booby-trapped it." In April 1975 L-dopa was discontinued and he was started on a combination (Sinemet) of L-dopa and carbidopa, an inhibitor of peripheral decarboxylation thought to increase the amount of L-dopa available to the brain for conversion to dopamine. He appeared to do well initially on L-dopa/carbidopa, 750/75 mg per day, but gradually became concerned that his family was putting drugs in his food to interfere with the antiparkinsonian medication. He became openly hostile and verbally abusive toward family members. The dosage was gradually lowered to 250/25 mg per day. At this dosage the patient again had symptoms of parkinsonism and the hostility and suspiciousness recurred. He was admitted to the psychiatric hospital after striking his son.

On admission, he manifested depression and symptoms of parkinsonism. He denied delusional thinking. Initially he was treated with amitriptyline and appeared to do well on 100 mg/day. He was discharged but developed confusion and visual hallucinations and was readmitted in early February. The confusion and hallucinosis resolved when amitriptyline was withdrawn. He was somewhat angry and delusional, and his parkinsonism appeared to have worsened. The L-dopa/carbidopa dosage was increased to 500/50 mg daily and 5 mg/day of haloperidol was also prescribed. Three days later he was calm and reasonable but could not walk without falling. Haloperidol was discontinued and L-dopa/carbidopa was increased gradually to 1500/150 mg per day. One week later, he was walking well and seemed free of parkinsonian symptoms but he was restless, cheerful, talkative, and appeared manic. He soon became angry and threatening. The dosage of L-dopa/carbidopa was reduced to 1250/125 mg per day, and he was started on 1200 mg/day of lithium carbonate in late February (serum lithium level of 0.8–1.2 mEq/liter). His belligerence disappeared, his mood improved, and he was discharged. The emergence of dyskinesias led to reduction in L-dopa/carbidopa to 625/62.5 mg per day—a higher dose than he had previously tolerated without lithium.

He continued to do well until May, when he developed insomnia and suspiciousness and was readmitted. He was angry at his family because they had mentioned placement in a nursing home. An attempt was made to add chlorpromazine to his treatment, but the drug was discontinued after he developed a confusional state with benztropine. He was finally able to return home on a regimen of 1200 mg/day of lithium carbonate and 500/50 mg per day of L-dopa/carbidopa. His wife was instructed to leave the house when he behaved inappropriately (which proved to be unnecessary after the first few such events). He reportedly did well for another four months.

At that point I contacted the family, who said the patient had had some difficulties in October, apparently similar to his original problems. The neurologist had had him hospitalized and taken off all medications. He was started on amantadine, with excellent results for the next 2 weeks. He then attacked his wife with a knife and was committed to a state hospital.

Discussion

Several factors in addition to L-dopa contributed to this patient's psychopathology—his life-long suspiciousness, his perception of himself as helpless because of his neurological illness, and his wife's meek and fearful response to his outbursts, which was gratifying in that it allowed him to feel powerful. However, it is clear that the amount of manic and paranoid symptomatology was correlated with the L-dopa dosage. Although lithium did not completely eliminate his accusatory behavior, it did allow treatment with larger doses of L-dopa than he could have tolerated otherwise.

The use of lithium to control L-dopa-induced psychosis has been reported before. Lithium was effective in one patient who had manic symptoms (4). In anoth-

Dr. Braden is Assistant Professor of Psychiatry, Brown University; he is also Staff Psychiatrist, Butler Hospital, 345 Blackstone Blvd., Providence, R.I. 02906.

er case, lithium controlled one patient's manic symptoms for only 2 weeks and was of minimal effectiveness in four patients with unclear symptomatology (5). Lithium may be useful when the dose of L-dopa cannot be reduced, especially since neuroleptics usually worsen parkinsonism symptoms.

Neuroleptics are thought to act by blocking dopamine receptors (3), so it is not surprising that they reverse both the therapeutic and toxic effects of L-dopa. In the case reported here, lithium apparently acted by a different mechanism, controlling the patient's manic and paranoid symptoms without noticeably worsening his parkinsonism (and without controlling L-dopa-induced dyskinesias). It has been suggested that lithium and L-dopa interact because each affects norepinephrine metabolism (4). Another possibility is that L-dopa induces behavioral changes by dopaminergic mechanisms, as is commonly thought, and that lithium acts at a different but functionally related brain site. This explanation is consistent with the wide overlap in clinical indications for lithium and the neuroleptics and should be considered in interpretation of research on model psychoses in animals.

Abuse of Antiparkinsonian Drugs by Psychiatric Patients

BY KATHERINE MACVICAR, M.D.

Trihexyphenidyl (Artane) and benztropine (Cogentin) are anticholinergic drugs that are widely used in psychiatric populations to control extrapyramidal symptoms due to phenothiazines. Like atropine and scopolamine, for which they are synthetic substitutes, these drugs have the propensity to cause CNS side effects ranging from mild confusion to toxic delirium (1). Other physical signs of toxicity include the usual signs of atropinism: dilated pupils, flushed dry skin, constipation, tachycardia, elevated blood pressure, severe dryness of the mouth, and ataxia. Paranoid trends are the outstanding feature of the toxic psychosis, and disordered time sense and hallucinosis are almost ubiquitous. Trihexyphenidyl is also reported to have a euphoriant effect in some patients, which may predispose the drug to abuse (2).

However, deliberate abuse of these drugs in the United States is apparently quite rare; there are only a few reports in the literature. This has not been the case in other countries. In Britain, where trihexyphenidyl was available without prescription prior to 1964, it was young people for its hallucinogenic proper- On occasion it was also unwittingly ingested duals who believed that they were taking Poland there was a report of 20 cases of deliri- te in young people who had taken tri- nidyl for narcotic effects (4). The low incidence of abuse in this country must result in part from the fact that the drugs are available only on prescription; also, more pleasant and relatively cheap hallucinogens are readily available. Several major drug abuse clinics in the San Francisco area reported that they had not encountered patients who abused antiparkinsonian medication. However, a similar clinic elsewhere in the country documented several cases of toxic psychosis due to benztropine, one of which was a deliberate overdose by a schizophrenic patient (5).

There may, however, be another reason for the scarcity of such reports, a reason related to the nature of the population that is likely to have access to the medications. Aside from their use in the treatment of arteriosclerotic and idiopathic parkinsonism, where they have been at least partly replaced by L-dopa, these drugs are most frequently used in psychiatric populations; thus, the excitement, paranoid ideation, and hallucinosis characteristic of toxic reactions may be easily missed because these symptoms are commonplace and inherent in the primary diagnosis. In addition, the toxic symptoms generally remit within 24–48 hours after the drug is discontinued and may be gone before an adequate evaluation can be made. In fact, the patient I will describe was hospitalized with an acute toxic psychosis due to trihexyphenidyl, and the true etiology was unknown until the patient later revealed his intake of the drug. Other reasons given for the low incidence of reactions to antiparkinsonian medication are the relative youth of schizophrenic patients, the tendency of phenothiazine and antispasmodic side effects to cancel themselves out, and the

icar is in private practice; she is also Staff Psychiatrist, emorial Hospital, Berkeley, Calif., and a candidate-in- n Francisco Psychoanalytic Institute. Address reprint r. MacVicar at 2702 Dana St., Berkeley, Calif. 94705.

pharmacologic resistance characteristic of schizophrenia (3).

Types of Toxic Reaction

Toxic reactions to antiparkinsonian drugs may be subdivided into 1) reactions to therapeutic dosages due to unusual sensitivity, and 2) reactions to overdoses. Toxic reactions have been reported in psychiatric patients who received the drugs in normal doses in conjunction with phenothiazines (6, 7). It has been suggested that narcotic users may be particularly sensitive to small doses of antiparkinsonian agents because narcotics diminish the rate of release of acetylcholine from nerve endings in both the peripheral and central nervous systems (5). There have been a number of reports (3, 8) of overdoses of the drugs with suicidal intent. Their use by presumably normal young people for "kicks" or for hallucinogenic purposes seems to be confined to other countries.

Misuse by Psychiatric Patients

This type of misuse has been reported by a few authors. Bolin (9) described a 32-year-old woman with marked hysterical features and masochistic preoccupations who developed a spastic torticollis, together with marked anxiety and depression. Trihexyphenidyl, 2 mg q.i.d., was effective in improving the symptom, but it also made her feel somewhat euphoric. As the stresses in her life increased, she began to take more of the drug, eventually reaching a dose of 24–30 mg/day. She then developed a toxic psychosis with marked paranoid preoccupation, confusion, and signs of atropinism. In this case, the euphoric effect led to ingestion of high doses of the drug.

Another case was reported (5) of a 24-year-old paranoid schizophrenic, a known abuser of other hallucinogenic drugs, who was taking 2 cc of I.M. fluphenazine enanthate every 2 weeks and 1 mg benztropine b.i.d. He developed a toxic psychosis after ingesting 12 benztropine tablets in order to get high. The same author cited three cases of narcotic addicts who overmedicated themselves with benztropine, precipitating toxic psychoses. These cases and the following one illustrate the potential hazards of antiparkinsonian medication in patients who have a history of drug abuse.

Case Report

The patient, a 30-year-old paranoid schizophrenic man, for 3 months had been taking 2 mg of trihexyphenidyl b.i.d. for alleged dystonic reactions to haloperidol. He did not reveal his misuse of trihexyphenidyl for some time, until he came to a point in his therapy at which he felt guilty about the misuse and wished to give it up. This patient was aware that phenothiazines tend to antagonize the effects of anticholinergic drugs and therefore refrained from taking phenothiazines the day before ingesting the trihexyphenidyl. He would take about 15 mg of trihexyphenidyl, which brought on a toxic psychosis with visual hallucinations that he found pleasurable, along with dry mouth, constipation, and nausea. On one occasion the patient took 50 mg of the drug and his behavior became so bizarre that he was picked up by the police and taken to a hospital in another area for observation. The true etiology of his psychosis was completely undetected; it was assumed to be an exacerbation of his preexisting schizophrenia. The patient reportedly introduced several of his friends to the drug, but most of them did not greatly enjoy the effects.

Aside from the euphoriant effect, a motive that he shared with the previously described patients, this man also enjoyed the feeling of being friendly and talkative that the drug gave him. It has been reported (3) that subjects feel a strong need to externalize the trihexyphenidyl experience and to communicate it to others, in contrast to responses to LSD and mescaline, which are dominated by an intense introspective preoccupation. The drug helped this patient to feel less isolated and also actively produced psychotic symptoms, which he usually experienced passively. At times the patient also used other psychedelic drugs to produce altered states of consciousness and hallucinations, presumably for similar motives. Apparently these benefits outweighed the unpleasant atropinelike effects of the drug, and he continued this pattern of use for some time.

Discussion

Deliberate abuse of antiparkinsonian medication for its euphoric and hallucinogenic effects has been reported only rarely in this country. However, there are many reports of abuse of proprietary medications containing belladonna alkaloids, which have very similar effects to the antiparkinsonian drugs. Since antiparkinsonian drugs have been abused in other countries, one must assume that the fact that they are controlled substances has prevented widespread misuse in this country. However, one should keep in mind the potential for abuse when prescribing these drugs, particularly with patients who have abused other drugs in the past.

These cases emphasize the need to exercise caution in prescribing antiparkinsonian drugs. It has been recommended (10) that they should not be prescribed prophylactically in patients taking phenothiazines but should be used only to bring extrapyramidal symptoms under control, and then in the lowest possible effective doses. Extrapyramidal symptoms rarely persist longer than 3 months; thus, patients on long-term medicati
usually do not require antiparkinsonian dru
should also have an index of suspicion in pati
keep requesting the drugs and in those with a
toward drug abuse.

Danger of Overreliance on Computerized Cranial Tomography

BY CHARLES E. WELLS, M.D., AND GARY W. DUNCAN, M.D.

Each advance in diagnostic technology has the potential for misuse. Computerized cranial tomography (CT scan) has enormously expanded the physician's capacity for visualizing intracranial structures and is being used increasingly in the evaluation of neuropsychiatric problems (1). However, the CT scan, like all laboratory techniques, is subject to misapplication. We recently studied two patients who were misdiagnosed by highly trained physicians as having progressive dementias on the basis of relatively minor changes in the CT scan, in spite of conflicting clinical and laboratory data. We report these cases in order to 1) caution against overreliance on CT scan observations with our limited knowledge of this still-new technique, 2) highlight the danger of using an isolated laboratory finding to establish a diagnosis when confirmatory evidence is lacking, and 3) emphasize that dementia is a clinical syndrome (2), the diagnosis of which rests on the congruence of clinical and laboratory data.

Case Reports

Case 1. A 36-year-old man was admitted complaining of memory loss and confusion. He had been healthy until a motor vehicle accident 23 months earlier when his head, neck, and shoulders were injured; he was unconscious for only a few seconds. Afterward he complained of head and neck pain, but no serious damage was suspected. His performance as a self-employed plumbing contractor was unremarkable until 3 months later, when he began to concentrate poorly, made errors in estimates, and started to lose money. He gave up his business and since then has worked only intermittently at undemanding jobs.

The patient's complaints multiplied. His headaches, which were initially episodic and severe, improved, only to be replaced by disabling pains in his neck, shoulders, arms, and back. He developed memory failures, including losing his train of thought during conversations, finding himself in a room at home and not remembering how he got there or why, and forgetting to pay bills. His wife reported that his personality changed and his irritability increased. Psychological evaluation (done elsewhere) suggested organic dysfunction and CT scan was interpreted as showing mild to moderate cortical atrophy. He was diagnosed as having dementia, possibly secondary to trauma. The persistence of his disabling symptoms led to hospitalization for reevaluation.

The patient was alert and cooperative. Despite considerable pain, he attended to long interviews with interest and concentration, giving a detailed, complex history clearly and coherently and arranging details in correct temporal order. He easily recalled names of physicians, medications, and dates that marked the course of his medical care. He appeared both anxious and depressed but was unaware of these affects. Mental status examination increased his anxiety, but his performance was commensurate with his educational attainments. General and neurological examinations were normal.

Neuropsychological test data (Wechsler Adult Intelligence Scale [WAIS] grooved pegboard, Wechsler Memory Scale, memory for objects, trail making, Wisconsin card sort, Bender Visual Motor Gestalt Test, and tactual performance test) were inconsistent with organic brain dysfunction, and his estimated full scale IQ was 100. Personality data (Rorschach, Minnesota Multiphasic Personality Inventory, Thematic Apperception Test, and sentence completion) indicated inner turmoil bordering on panic, with anxiety, depression, and marked somatization.

The cerebrospinal fluid, radiographs of skull, chest, and spine, and EEG with nasopharyngeal leads were normal. CT scan was again interpreted as showing mild cortical atrophy.

The authors are with the Vanderbilt University School of Medicine, Nashville, Tenn. 37232, where Dr. Wells is Professor of Psychiatry and Neurology and Vice-Chairman, Department of Psychiatry, and Dr. Duncan is Assistant Professor of Neurology.

The authors wish to acknowledge the assistance of Denton Buchanan, Ph.D., who performed the psychological tests.

The mental status examination, neuropsychological testing, and other data except the CT scan failed to support the presence of organic dementia. The emphasis on cognitive dysfunction as a complaint, the communication of distress, the highlighting of failures, and memory gaps for specific periods were consistent with a pseudodementia which, with the manifest anxiety and depression, led to a diagnosis of serious posttraumatic neurosis.

Case 2. A 47-year-old man was seen for neuropsychiatric evaluation 4 weeks after an automobile accident because he and his wife would not accept the diagnosis of progressive dementia made earlier by a consulting neurosurgeon.

There was no history of neurologic or psychiatric dysfunction. The patient was a college graduate with a successful career who had functioned well in a highly skilled technical position until the automobile accident. He was not unconscious after the accident, but he complained of headache, appeared befuddled, and was hospitalized for observation. His symptoms abated, and he was discharged after 3 days. At home he experienced decreasing symptoms of headache, impaired concentration, low frustration tolerance, and unsteady gait. After 10 days he felt ready to resume work, but he experienced a severe episode of vertigo on bending that persisted for several hours. He was admitted to the neurosurgical service of another hospital, where the vertigo quickly subsided but his previous symptoms exacerbated. A build-up of high-amplitude slow activity with hyperventilation on EEG was interpreted as a "paroxysmal dysrhythmia," and "some mild cortical atrophy" was described on computerized tomography.

The patient and his wife were told that the CT scan showed brain atrophy which probably reflected a progressive dementing process, most likely predating the accident. Their unwillingness to accept the diagnosis resulted in referral for reassessment.

On admission to the hospital the patient complained of headaches, unsteady gait, fuzziness of vision, trouble concentrating, losing his train of thought, anxiety, and decreased frustration tolerance. He was alert, cooperative, anxious, and worried. He gave a clear, detailed, and accurate history, although he lost his train of thought several times. Each time he recognized this, called it to the examiner's attention, and proceeded appropriately. Although the tasks of the routine mental status examination appeared to give him trouble, his responses were accurate. The neurological examination was normal except for some unsteadiness when he turned quickly.

Skull X-rays, waking and sleeping EEG, and extensive otologic evaluation revealed no significant dysfunction. The WAIS, Wechsler Memory Scale, memory for objects, tactual performance test, Bender-Gestalt, trail making, sentence completion, MMPI, TAT, and Rorschach revealed no evidence of organic dysfunction. Full-scale IQ was 118 (verbal score=119, performance=114). There was considerable evidence of depression, anxiety, and somatization. Repeat CT scan revealed frontal convolutions slightly narrower and sulci slightly wider than usual.

The patient's symptoms were typical of those which follow mild cerebral trauma without brain damage. The symptoms had been exacerbated and prolonged by the fear that resulted from the episode of vertigo and the diagnosis of dementia. Clinical examination, behavioral observations, and psychological tests were inconsistent with dementia. He was discharged with a diagnosis of posttraumatic cerebral dysfunction with a good prognosis. Follow-up six weeks later showed resolution of most of his symptoms.

Discussion

The two patients we have described complained of symptoms that suggested dementia, but the history in each case was atypical of the usual dementing process (2), and mental status examination and behavioral observations were incongruent with dementia (3), as were ancillary diagnostic procedures except the CT scan. In other words, both patients presented clinical findings typical of pseudodementia (4–6) but were diagnosed as demented, almost solely on the basis of minimal features of the CT scan.

Computerized cranial tomography is a new and important diagnostic aid that has significantly increased our ability to measure brain size and contour safely and comfortably. However, standards of normality have not been firmly established (7), especially for varying ages, and even if they were, it would be dangerous to assume that a pattern noted on the CT scan invariably resulted in a specific clinical disorder. Fox and associates (8) observed that patients with moderate to severe dementia usually have moderate to severe brain atrophy demonstrable on CT scan. They suggested that absence of significant atrophy in dementia indicates a reversible process. We recommend that if a patient who appears demented has a CT scan revealing no more than minimal atrophy, the presence of dementia itself should be critically examined.

In the two cases we have described, the observations reported from CT scan probably represent normal variations of no pathologic significance. When the diagnosis of a clinical syndrome rests on an isolated laboratory observation, the physician should critically examine the reliability of the diagnostic procedure.

We reiterate that dementia is a clinical syndrome and the diagnosis rests on congruence among history, clinical behavioral observations, and ancillary diagnostic procedures. No single feature (history, mental status, psychological testing, EEG, or CT scan) establishes the diagnosis, and the physician who assigns preemptive diagnostic significance to a single measure is likely to err.

EEG Sleep in a Child with Severe Depression

BY JUDITH KANE, R.N., M.S.N., PATRICIA COBLE, R.N., C. KEITH CONNERS, PH.D., AND DAVID J. KUPFER, M.D.

Depressive illness in children has become an area of increasing concern because it may severely impair an otherwise healthy child's scholastic and social adjustment (1). However, as numerous authors have pointed out, it is extremely difficult to diagnose depression in children because the clinical picture may vary depending on age and developmental level (2–4). Clinicians have long noted the prevalence of disrupted sleep as part of the symptom complex (5). EEG sleep studies in adults with depression have augmented our understanding of these depressive illnesses (6), but we are not aware of any such studies of children. We have begun to examine the EEG sleep of depressed children in cooperation with the inpatient children's psychiatric service in our clinical research setting. In this report we shall describe the EEG sleep and clinical data of a child who presented with severe depression.

Clinical History

This was the first psychiatric admission for Mary, an 11-year, 4-month-old girl who had been referred for evaluation of withdrawn behavior, increasing school difficulties over the past year, and suicidal threats over the previous several weeks. Her parents noted that she had become "very quiet and shy, answering only in whispers," her school performance had worsened, and she had fewer peer relations. At home she became exquisitely concerned about cleanliness and engaged in handwashing rituals and various phobic behaviors. On occasion she would lock herself in the bedroom or bathroom, refusing to come out or threatening to jump out the window. After an unsuccessful trial of individual psychotherapy, Mary's parents became frightened that she would carry out her suicidal threats and she was admitted to the children's psychiatric intensive care service.

Mary was a tall, slender girl with blond hair and some early breast development. Her demeanor was shy and demure. She appeared anxious, carried herself in a rigid, constricted manner, and was hypoactive in motor behavior. She was essentially nonverbal, avoiding eye contact and answering only direct questions with a nod of her head. Her affect was depressed. Her developmental history and medical history were unremarkable. Family history, as far as could be ascertained, was negative for the presence of major psychiatric disorders. Physical examination on admission, routine laboratory tests, chest X-ray, and EEG were all within normal limits. Psychological testing revealed a girl of average intelligence who did not appear to be suffering from any organic deficit or cognitive dysfunction. The predominant picture was that of an affective disorder, leading to a diagnosis of depressive reaction of childhood with suicidal ideation.

Mary was treated with both a tricyclic antidepressant and a phenothiazine (25 mg of imipramine, b.i.d. and 5 mg of trifluoperazine, h.s.). Her depressive symptomatology showed a marked improvement within 3 weeks and she was discharged on the same drug regimen.

Sleep Studies

Our techniques for studying sleep in this setting and our methods of scoring EEG sleep records have been reported elsewhere (6). Children visit the laboratory prior to their scheduled study for a "grand tour." They are shown the bedroom where they will sleep and are introduced to the laboratory staff. In addition, the nursing staff of the children's unit have been given a set of electrodes and a junction box that they routinely use to familiarize the children with the process of being "wired up" before coming to the sleep laboratory. During the actual study period, a member of the nursing staff not only accompanies the child to the sleep laboratory but stays in the area throughout the

TABLE 1
Mean Sleep Characteristics of a Prepubertal Depressed Child

Measure	Mean Observed Values
Sleep latency (minutes)	55.5
Intermittent wakefulness (minutes)	20.5 (4.6%)
Time spent asleep (minutes)	443.5
Sleep efficiency (percent)*	82.7
Time in stages (percents)	
Stage 1	3.2
Stage 2	43.3
Stage 3	6.8
Stage 4	24.1
REM latency (minutes)**	87.0
Stage 1-REM (percent)	22.0
REM activity units***	147.0
REM density‡	1.88
Number of REM periods	3.5

*Calculated by dividing the amount of time spent asleep by the total recording period.
**Number of minutes from sleep onset until the onset of the first REM period.
***An estimation of rapid-eye-movements on a scale of 0–8/minute of REM sleep.
‡Determined by dividing the REM activity units by the REM time (minutes of REM sleep).

night. All-night EEG sleep recordings were obtained for 3 consecutive nights following the initial period of formal evaluation and at a time when Mary had been drug free for more than 14 days.

Results

The sleep pattern in this depressed child was characterized by a significant disturbance in sleep continuity. This disturbance did not appear to be restricted to any one type of arousal but was different on each of the study nights. Early morning awakening was the most prominent on night 1, difficulty falling asleep on night 2, and intermittent wakefulness on night 3. Her overall sleep efficiency (82.7% for nights 2 and 3) was significantly decreased when compared to normal values in this group, even when the first night was omitted because of the possible influence of adaptation to the laboratory.

While various measures of sleep architecture appeared to be consistent with those reported in normal controls, the relatively stable but persistently shortened REM latency was of particular interest (see table 1). Although normal values in this age group show considerable variability (137.5±34.5 minutes), the REM latency values for this child still appear to be at the lower end of that range and are significantly shorter than the mean value for this age group (7).

Discussion

In general, there is a paucity of information regarding EEG sleep of children who have a major childhood psychiatric disorder. A few studies do exist on various aspects of EEG sleep in psychotic and autistic children (8, 9), but we are aware of no reports that specifically address the sleep of children with depressive syndromes. There is much variability of normative EEG sleep values in children, but Mary's sleep did show some distinct aberrations, particularly the marked sleep continuity disturbance. The mean sleep efficiency of 82.7% for nights 2 and 3 is much lower than values reported in normal girls of this age. Also noteworthy is the abnormally short REM latency, which remained low regardless of the type or extent of sleep continuity disturbance experienced. Other REM sleep parameters, although variable, seemed to be more related to the type and severity of her sleep discontinuity.

These findings are very interesting; there are some similarities to findings in depressed adults. However, one cannot generalize from this single case study. Such findings can perhaps best serve to raise a number of relevant questions for future investigation.

1. What are the sleep characteristics of larger samples of depressed children and how do they compare with those of children in other diagnostic groups?
2. Are there any relationships between certain sleep parameters and specific symptomatology in childhood disorders?
3. Can developmental changes be distinguished from diagnostic changes in children?
4. Can certain alterations in the sleep patterns of children be used as more objective indicators of treatment strategy, particularly with regard to the efficacy of major pharmacologic intervention?

Fluphenazine Decanoate During Pregnancy

BY MICHAEL F. CLEARY, M.D.

The introduction of long-acting phenothiazines for the treatment of psychotic patients over a decade ago (1, 2) was stimulated in part by the need to ensure consistency of medication intake and to avoid relapse and multiple hospitalizations (3).

There has been apprehension about such treatment for severely psychotic women during pregnancy. The responsibility for continuation of phenothiazine therapy rests with the clinician; manufacturers' comments in the *Physicians Desk Reference* usually indicate that the safety of the use of such drugs during pregnancy has not been established and that the possible hazards should be weighed against the potential benefits. The mechanism of the therapeutic action of these drugs is unknown. This paper describes the use of fluphenazine decanoate throughout pregnancy in a 32-year-old primiparous schizophrenic patient.

Case Report

When the patient was first seen in January 1972 she was 29 years old and had been married for 8 years to an engineer who was 5 years her senior. This was the first marriage for both and there were no children, although the patient had had a first-trimester miscarriage in 1968 after an automobile accident.

She had been in psychotherapy in another state and wished to continue. At the time of her self-referral, the patient had been taking oral phenothiazines for 5 years; her dosage then was 800 mg/day of chlorpromazine and 30 mg/day of trifluoperazine. In addition, she took 2 mg/day of trihexyphenidyl HCL. Her history included another automobile accident in 1965, in which she had suffered a concussion; after the accident she had a psychotic episode. Her first psychiatric hospitalization was at age 15. During a later hospitalization she had a course of 5 ECTs. She was one of a family of four; no one else in the immediate family had been mentally ill. The dosage of oral phenothiazines was progressively reduced during the 15 months after I began treating her but was increased when the patient began to appear irrational and expressed delusional ideas; she also became preoccupied with religious concepts and developed an interest in the occult. She managed to give up smoking but seemed to require larger doses of phenothiazines when she abstained from tobacco. She had stockpiled drugs from earlier prescriptions and once threatened to take an overdose after calling a suicide prevention center.

In October 1973, she was admitted to a private psychiatric hospital and was started on 2 cc of I.M. fluphenazine decanoate every 3 weeks because of her unreliable drug ingestion, her habit of stockpiling medication, and her suicidal tendencies. After her discharge from the hospital in November 1973, she continued to be seen in individual psychotherapy; the same dosage of fluphenazine decanoate was given until January 1975; 2 mg of benztropine mesylate b.i.d. was also prescribed but she began to take it only sporadically. She conceived in early January 1974, with an expected delivery date of October 8, 1974. The possible hazards of phenothiazine use early in pregnancy were discussed with the patient and her husband, and they concurred with the therapist's recommendation that the fluphenazine be continued. She had resumed smoking and was drinking four or five cocktails each evening. She developed occasional vomiting during the first trimester and experienced weight gain and elevated blood pressure (140/100) in the second trimester. Her cigarette consumption reached a peak of four packs daily. Latent homicidal ideas were noted late in her pregnancy, and her behavior continued to be bizarre, explosive, and unpredictable.

A healthy male infant weighing 7 pounds, 7 ounces (3.38 kg) was delivered by Caesarean section 9 days after the expected date following the failure of oxytocin to induce labor. The Apgar score of the baby was 8 after 1 minute and 10 after 5 minutes. The patient remained in the hospital for 6 days—fluphenazine decanoate (2 cc I.M.) was given 4 days postpartum. This dose was repeated 4 weeks later and the patient's regular dosage schedule (every 3 weeks) was then resumed.

Four weeks after delivery, the pediatrician thought the baby had minor extrapyramidal manifestations, as has been previously reported by Hill and associates (4). He had been breast fed for 5 days. The extrapyramidal symptoms—or withdrawal symptoms from fluphenazine—responded readily to diphenhydramine elixir. Two months after delivery, the infant was healthy and weighed 10 pounds, 4 ounces (4.66 kg). The patient developed somatic delusions, became agitated and paranoid, and was readmitted to a psychiatric hospital. After discharge from the hospital, she sought treatment from another psychiatrist and some months later left the state. She continued to write letters to her therapists that indicated the persistence of a schizophrenic thought disorder.

Subsequent communications included a phone call from the patient in June 1976 in which she said the baby, then 20 months old, was healthy. She also sent a photograph taken on his second birthday that showed an apparently well-nourished, well-developed, and alert child.

Dr. Cleary is in private practice at 7350 East Stetson Dr., Scottsdale, Ariz. 85251.

Prompt Publication Policy

The *Journal* would like to remind authors who are particularly interested in early publication (whether to establish priority of an idea, reveal innovative results of new research, or for other pressing reasons) of its prompt publication policy. Under this policy, short (maximum of six double-spaced pages) manuscripts will be considered for publication in the Brief Communications section of the first available issue. These manuscripts must still undergo expert scrutiny before being accepted, and two months must be allowed for the printing process. However, the time required for publication of these short articles can be lessened considerably.

Authors who would like to have their manuscripts considered under this policy should indicate this desire, as well as the reasons for it, when they submit their manuscripts.

LETTERS TO THE EDITOR

This section contains reactions to Journal *articles, statements of opinion, comments on Association activities, requests for information, etc. Letters should be submitted in duplicate to the Editor, who makes all decisions regarding publication. Letters must be typed double-spaced throughout and should not contain more than 500 words and 5 pertinent references. Criticisms of published articles will automatically be sent to the author(s) for response. Letters will be edited for clarity and conformance with* Journal *style. We regret that we cannot inform writers of the disposition of letters or return those which are not printed.*

On Existence of Dangerousness

SIR: The type of patient described by Victor R. Adebimpe, M.D., in "Physical Violence in the Concept of Dangerousness: A Case Report" (February 1977 issue) is familiar to all psychiatrists. For those who enjoy categorizing patients, Mr. A certainly fulfills the usual criteria of primary affective disorder, manic type. I have no reason to doubt that the description of Mr. A's behavior is accurate.

However, I have grave concerns about the attitude Dr. Adebimpe seemed to display, which reflects an apparent lack of concern with intra- or interpersonal dynamics or conflicts. The attitude also seems to betray a feeling that the doctor has more wisdom, prescience, responsibility, and authority than the patient, the judge, or the Constitution. Dr. Adebimpe apparently feels that the patient's disagreement with him was a significant indicator of illness. This animosity from the patient toward the doctor seems in some way to arouse within Dr. Adebimpe urges to protect the patient through further confinement, forced medication, and labeling him as dangerous.

Violence is frequently the result of interpersonal conflicts. The identification of one of the actors as "sick" only reinforces the behaviors of the antagonists, frequently resulting in ostracism of the "sick" person, as this case demonstrates.

If we, as a society, insist on the incarceration of individuals on the basis of presumed dangerousness, I for one would prefer to see persons locked up for driving while intoxicated or for child abuse. The whole notion that some physician can invoke a diagnosis as a basis for incarceration is frightening to me, and I think it should be frightening to anyone concerned with human liberty and freedom.

I applaud the attorney, judge, and patient in this case. The willingness of the attorney and judge to consider this patient's rights is refreshing, even if they did not, or could not, ignore the accusations of the physician.

Dr. Adebimpe mentions that a trial was held. I suspect he is referring to a commitment hearing, but his choice of the word "trial" is further evidence of the attitude that this patient was "guilty" of something. I would rather have seen a trial based on the patient's assault on his wife than a trial regarding his mania.

I do not blame Mr. A for not following the medication instructions, for failing to make or keep appointments for follow-up, or for "refusing to recognize his illness"—he seems to have had good reason to suspect his physician's allegiance. Although it may not have been intentional, the psychiatrist in this case gave primary concern to the wife's fears, not to the patient's rights. I hope Mr. A will someday encounter a therapist with whom he can feel safe and be safe. Only then will Mr. A be able to recognize his self-defeating behavior.

I must have missed some major point in the article, because I could not follow Dr. Adebimpe's final remarks. It seemed to me that Mr. A continued living with the burden of impending death (i.e., his coronary disease). In addition, Mr. A was apparently able to carry out an independent existence, to move, to apply for Veterans Administration benefits, and to refrain from aggression against the wife who abandoned him. In other words, the patient refused to comply with the doctor's predictions of dangerousness. Although I personally would not enjoy enduring the patient's posthospitalization existence, I do not see reason to invoke the powers of the state to protect him from that existence.

When Dr. Adebimpe states, "The answer is clear," I do not know what he means. What is the question? If the question is "Should all manics be locked up?" or "Should all mentally disturbed persons be locked up?" or "Should a person be locked up because a psychiatrist predicts violence?" my answer is a fervent no. However, if the question is "Should dangerous people be locked up?" I would say yes, but I would need evidence that mortal danger is present. I would require confinement not because someone is "sick," but because he/she is sick *and* dangerous as demonstrated by previous behavior. I would rely on legal definitions of offensive acts and penalize the individual for these acts, not for his/her illness. In any case, I would not call a psychiatrist into the court proceedings until the trier of fact had found the facts and made conclusions of guilt or innocence based on those facts. If we must release "sick" people who have committed no serious offense, so be it. Let there be consequences for behavior proportional to the offense and let them be uniformly applied.

We in Missouri are attempting to remedy past abuses of citizens' rights with Senate Bill 275; other states have made such changes already. But providing for due process is only a first step. Ultimately, we need to alter attitudes which hold that mentally disturbed persons should be subject to more, or more severe, sanctions than others who commit similar offenses.

LAWRENCE R. DOSS, M.D.
Columbia, Mo.

Dr. Adebimpe Replies

SIR: A more leisurely reading of the article might reassure Dr. Doss that rather than adopting an omniscient posture, I attempted to acquaint the court with medical and psychiatric considerations that would have been applied to a decision for discharge had Mr. A been a voluntary patient. These included information about the intra- and interpersonal dynamics in the case. They were probability statements, not ex cathedra pronouncements, and none of the recommendations were intended to be instructions.

Psychiatric diagnosis was not invoked as a basis for incarceration. The patient's heart condition and lithium therapy required medical surveillance "ideally in an inpatient setting." His improved but continuing mania prevented him from seeing that assaulting his wife and daughter had been out of character. Therefore, "immediate release was ill-advised [because] treatment for a week or 2 beyond the 10-day period of the emergency commitment might give the patient a better chance for optimal response to therapy." His previous record of outpatient attendance was bad.

Obviously, the point of the article needs to be more concretely stated. There was no question of "refusing to comply with the doctor's prediction of dangerousness," since my testimony was that the risk of deliberate acts of violence was low. The critical issue is that if, as a result of mental illness, a man's actions are unintentionally detrimental to his own health and to the social and economic well-being of his family, do we need to wait for him to hold a gun to his head or theirs before deciding that some decisions must be made for him until he gets better? Opinions are still divided on the issue, because one of those decisions is that his liberty be temporarily curtailed.

This case illustrated some possible consequences of insisting on liberty at all costs. Mr. A became estranged from his wife and daughter, not the kind of "independent existence" that most people might envy. His heart condition became worse, and the decision to see a cardiologist was no longer optional. The necessity of discontinuing lithium carbonate showed that his physician's concern about monitoring the early stages of therapy with this drug was justified. The continuation of his mania for 2 more months may have been the result of outpatient treatment, but we cannot be sure. In this locality the average length of inpatient stay for his condition is much shorter than that.

The outcome in this case suggests that if we define dangerousness only as "the probability that the individual will inflict harm on himself or others in a specific physical manner," we are obliged to give some patients liberty at the risk of consequences that we would not ordinarily wish for ourselves. In addition, we may deprive them of the right to the type of treatment they themselves might have requested had their judgment been intact.

The question is, "Which is preferable: worsening untreated heart disease, prolonged episode of mania, forced estrangement from family and home, and transfer to another state, or 3 weeks of inpatient treatment?" Although some of these outcomes are the result of the unique court ruling, it is clear that when neither alternative is desirable, it is common sense to choose the lesser of two evils. Liberty is fine, but the best should not be the enemy of the good.

VICTOR R. ADEBIMPE, M.D.
Pittsburgh, Pa.

Subcategorizing Gilles de la Tourette's Syndrome

SIR: On the basis of our study of 450 patients with Gilles de la Tourette's syndrome (1), we suggest that there are eight types or subcategories of movement disorders presently subsumed under this diagnosis. The syndrome is a chronic, multiple-tic condition that begins in childhood and is characterized by involuntary, sudden, rapid, and purposeless movements and vocalizations that can include sounds, words, and coprolalia.

The eight subtypes and their characteristics are as follows:

1. Transient tic of childhood. The symptoms are indistinguishable from the initial symptoms of Tourette's syndrome. The only difference is that the symptoms remit spontaneously within one year.
2. Subacute multiple tic of childhood or adolescence. The symptoms and clinical course are indistinguishable from Tourette's syndrome and last longer than one year, but complete remission occurs before or during adolescence.
3. Dystonic variant of Tourette's syndrome. This group includes patients whose movements have both a fast and slow or dystonic component. The tics of Gilles de la Tourette's syndrome are frequent, brief, rapid, sudden (lightning-like), and jerky. Patients in this subgroup have dystonic movements as well. These movements are slow, stretching, writhing, or manneristic squeezes, somewhat (but not exactly) like the symptoms characteristic of focal dystonia. The symptoms are not fully developed, however, and resemble partial, incomplete, or abortive forms of blepharospasm, torticollis, or writer's cramp. These dystonic symptoms respond less successfully to treatment with haloperidol.
4. Invariant tic symptoms beginning in childhood. These patients' symptoms begin in childhood and are characteristically more stable and constant than the variable and changing symptoms in Tourette's syndrome. In Tourette's syndrome, symptoms change slowly over time, with new symptoms replacing or being added to old ones. Symptoms wax and wane spontaneously, and the clinical course characteristically fluctuates. In this subgroup, although the symptoms also include variable, spontaneously changing multiple tics, the symptoms are fewer and less variable, show less spontaneous changing, wax and wane less, are more stable and stereotypic, and tend to remain the same throughout life. Our impression is that myographic recordings would differentiate tics from these muscular movements because they tend to be slightly stronger, definite, and vigorous. Vocal tics are less frequent and intense and have a different tonal character. These symptoms respond to treatment with haloperidol, although somewhat less successfully than the more classic tics of Tourette's syndrome.
5. Invariant tic symptoms beginning in adulthood. Symptoms in this group are similar to those described for group 4, except that they begin in adulthood, frequently during or after middle age. Only one or, occasionally, two tic symptoms are present.
6. Polymorphous perverse variant. These patients have a mélange of symptoms characterized by vivid, changing, and primitive sadomasochistic and polymorphous perverse sexual fantasies; excessive intense and bizarre thoughts and ideas; obsessive, compulsive, and echo phenomena; thought fixation; and fog states. A classic case of this type was described by Meige and Feindel (2) in a chapter entitled "The Confessions of a Victim to Tic," and several other case descriptions appear in the older literature.

7. Self-mutilation variant. Self-mutilation is a symptom of a small number of patients with symptoms otherwise similar to those of Tourette's syndrome. First described by Van Woert and associates (3) and suggestive of but not identical with the severe self-mutilation that occurs in children with Lesch-Nyhan syndrome, such patients have a tendency to severely bite their tongues, lips, or cheeks.

8. Treatment-resistant type. Patients in this group fulfill the classic criteria for Tourette's syndrome but fail to respond adequately to treatment. Despite considerable effort in titrating the dosage of haloperidol and the management of side effects over a long period of time, these patients (who represent less than 5% of the total group) develop side effects that offset the benefit of haloperidol. The side effects appear to be more of a problem than the tics. Clinically, these patients seem to be extremely sensitive to the extrapyramidal side effects of haloperidol. The possibility that they have another subcategory of movement disorder should be considered.

These variations in symptoms and clinical course may be different manifestations of essentially one illness or may represent different disease entities. These initial and preliminary clinical observations should be further evaluated by careful, controlled clinical and biochemical studies.

Improvement or Relief from Side Effects?

SIR: The article entitled "The Treatment of Acute Schizophrenia Without Drugs" by William T. Carpenter, Jr., M.D., and associates (January 1977 issue) raises several interesting questions. The authors suggest that these questions could be answered by careful scientific study, but their investigation was neither careful nor scientific. They acknowledged two major flaws in their study: 1) the failure to control treatment in either patient group, which reduces the value of any outcome comparison, and 2) differences in timing of follow-up, which also hinders meaningful comparison.

A third flaw involves the apparently haphazard use of medication. The authors indicate that drug prescription in the National Institutes of Health (NIH) sample was related to the patient's date of admission rather than symptom or prognostic status. If drug prescription was determined in this way, one must question both the objectivity of the staff in making key treatment decisions and the validity of the drug versus no drug comparison.

The authors conclude that treating acute schizophrenics without drugs is "feasible." However, the fact that the patients treated without drugs at NIH had a 35% rehospitalization rate within 9 months of discharge does not suggest that these patients did terrifically well.

The authors did not comment on the higher socioeconomic status of the NIH group compared with the International Pilot Study of Schizophrenia (IPSS) sample. Patients in the NIH group were significantly more likely to be in social classes I or II than the IPSS group ($p<.001$, chi-square test). Higher social class and mobility have been associated with better outcome (1–3).

The fact that, among those NIH patients treated with medication and then withdrawn from it (after an average of 46 days), significant improvement was noted during the no-drug period is not surprising given the following examples cited by the authors: "more spontaneity, fuller affect, less psychomotor retardation, and more social and work initiative." It appears that the authors were rating drug side effects, particularly akinesia (4), as psychopathology. This could certainly account for the "improvement" in these patients when drugs were withdrawn. No mention is made of examinations for extrapyramidal side effects or use of antiparkinsonian agents.

It is unfortunate when serious investigators address major issues with poorly designed studies and easily misinterpreted data that only serve to increase confusion.

JOHN M. KANE, M.D.
Glen Oaks, N.Y.

Dr. Carpenter and Associates Reply

SIR: We had hoped that our communication would encourage further consideration of several issues in the treatment of schizophrenia rather than evoking polemics. We have received several other communications that, by the nature of their praise or criticism, suggest we missed the mark. Perhaps this response will enable us to come closer to achieving our goal.

Our review of the literature suggests that the predominant treatment considerations in schizophrenic patients rest on a very narrow information base. What may seem to be important operating assumptions should actually be regarded as questions urgently in need of careful scientific study. In our report of observations and thoughts based on our experience with a treatment program at NIH, we carefully indicated that these observations were not from a study designed to compare different treatment approaches; we certainly did not represent our observations as providing any definitive answers. We did not have controlled treatment conditions in either patient group, and this does limit the value of the outcome comparisons. It was precisely for this reason that the question we addressed with these data was of limited scope. Was there evidence that patients receiving psychosocial treatment with little or no medication fared poorly compared with those receiving "usual" treatment?

A second flaw pointed out by Dr. Kane was the uneven

timing of follow-up evaluations. We called attention to this problem in our article, but in a footnote we presented data indicating that the unequal timing biased against the NIH patients and therefore did not undermine the conclusions we drew from these observations.

Dr. Kane discusses a third flaw, but his discussion seems to indicate a considerable difference in his views and ours on the clinical decision-making process. We discussed a probable indication (related to phasing in and phasing out of a particular treatment program) that the date of admission was an important variable in determining medication status in these patients. Many considerations enter into treatment decisions, and clinicians who view themselves as operating purely objectively without being influenced by the social setting in which they work are maintaining a view that is contrary to our understanding of the clinical decision-making process.

In regard to Dr. Kane's comment about the 35% rehospitalization rate, we did not claim that NIH-treated patients had done "terrifically well," nor did we provide a psychosocially oriented treatment during the aftercare period. Furthermore, the 35% rehospitalization rate does not compare unfavorably with a number of other studies in which maintenance antipsychotic medication was used. Dr. Kane ignores the immediately relevant information in our report, which indicated that the NIH patients had done at least as well as the drug-treated comparison group. Furthermore, those NIH patients who received antipsychotic drugs during hospitalization were slightly more likely to be rehospitalized during the follow-up period than patients treated without medication.

Whether one would expect schizophrenic patients to improve if medications were discontinued before discharge is a moot point. It is a common apprehension that clinical deterioration will occur when drugs are discontinued, and patients are generally left on medication throughout their hospitalization, even when clinicians expect the patient to take medication unreliably after discharge. Akinesia and sedation are often side effects of antipsychotic medication, and one would not be surprised to see the type of improvement we described as patients come off these drugs. However, it is important to consider this potential benefit in relation to clinical management. If, for example, side effects in some way mimic residual or defect symptoms of schizophrenia or induce apathy or demoralization, the immediate course of illness will be complicated by these side effects. We did argue that this was sufficient reason to discontinue drugs, but we did think that what happened when we took patients off drugs before discharge for purposes of the research protocols was worth mentioning.

Dr. Kane is correct in noting that there is a disproportionate representation of higher social classes in the NIH patients compared with the IPSS patients. This represents a minority of the patients and, taken in conjunction with the other extensive prognostic data, does not seem to undermine our conclusions. We apologize for this error and have since looked at the relationship between social class and outcome in the NIH patients. Using the nonparametric statistic tau and the Pearson product-moment correlation coefficient, we found no significant relationship between social class and outcome. A positive correlation was predicted, but the correlation coefficients were $-.17$ and $-.22$, respectively, both nonsignificant. This does not suggest that the influence of social class on course and outcome in schizophrenia has been overrated, but with relatively small numbers and with very few patients falling into the very lowest or very highest social classes, it is not a significant operating bias in this cohort.

We certainly share with Dr. Kane the view that serious questions should not be addressed with poorly designed studies and easily misinterpreted data, as our critique of the literature indicates. Our care in describing the nature of our data and the limitations of its interpretation was intended to discourage misinterpretation and to encourage open-mindedness regarding the optimum treatment of schizophrenia.

More on Exhibitionism in Women

SIR: In "Genital Exhibitionism in Women" (April 1977 issue) Marc H. Hollender, M.D., and associates did not mention in their review of the literature a paper I have written on the subject. The case I analyzed (1) clearly shows that genital exhibitionism by women can be a sexual perversion that is almost identical with that seen in men. The exposure of the genitalia was accompanied by masturbation and orgasm; it was also motivated by castration anxiety. One characteristic difference was the need for a fetish during the act.

A Middle Ground in Prophylactic Antiparkinsonian Medication

SIR: Recently, two children I had been treating with phenothiazines suffered dystonic reactions. In both cases I had warned the children's mother of this possibility, and I had supplied both mothers with small samples of benztropine mesylate. By the time the mothers called to express their concern they had already given the medication to their children; both crises passed within a half-hour. The mothers were very grateful that they had been prepared. One child was a 9-year-old boy being treated with 1 mg/day of haloperidol for Gilles de la Tourette's syndrome and the other was a 12-year-old boy being treated with thioridazine, 200 mg h.s., for severe childhood schizophrenia. Both boys are now receiving 2 mg/day of benztropine mesylate in addition to their phenothiazines.

I am writing about this situation because I continue to see both positive and negative communications regarding prophylatic antiparkinsonian agents. Many physicians believe that one should wait until problems occur before prescribing antiparkinsonian medication.

I like the idea of waiting until trouble occurs, but once it does the patient suffers while the family contacts the physician, who then has to call the pharmacy and prescribe the medication, which then must be picked up; meanwhile, the

patient is dystonic and very frightened. For that reason I now supply a small amount of antiparkinsonian medication to those patients I think are more likely to experience a dystonic reaction. This has worked out very well so far, as the two examples above illustrate.

I thought my experience might be of interest to other psychiatrists and physicians in view of the contradictory opinions on prophylactic antiparkinsonian medication. I feel a middle ground is a wiser course.

DIRK E. HUTTENBACH, M.D.
Marietta, Ga.

Creative "Restraints"

SIR: In "Children's Rights on Entering Therapeutic Institutions" (February 1977 issue) Derek Miller, M.D., and Robert A. Burt, J.D., used psychological insights to arrive at practical solutions that I would like to support with some of my own experiences. At our center in Austin, Tex., we have not yet experienced the courts' intervention in limiting parents from obtaining treatment of a protesting child. In our open rural setting, with a policy against any kind of physical structure into which a child could be locked, we have successfully treated many children thought to require closed settings because they have run away repeatedly. We agree with the authors' emphasis on symbolism and relations as being more important than physical structures in dealing with this problem.

During the early stage of treatment, we work hard to develop relationships of sufficient quality to ensure that the child who may run away will return. We use symbolic means of restraint, requiring "runaway risks" to wear gray sweatsuits called "pajamas." Since, according to our lore, one cannot elope in pajamas, the potential runaway must somehow sneak clothes (which is not difficult). Although our sweatsuits would attract little attention in the community, only two children (both psychotic) have run away wearing "pajamas." We also require a child who threatens to run away to stay with staff. If he/she needs further structure, we tie him/her to a staff member with an easily broken piece of kite string; this restrains the child only symbolically but gives support against impulsivity. We can then selectively interpret the situation (and the symbiotic conflicts involved), to for example, a 6-foot-tall muscular 16-year-old complaining bitterly of being prevented from running off by being bound to a 5-foot-tall, frail female staff member.

It would be easy to run away from our center by feigning cooperation for a few hours and then slipping off into the woods near the highway. Such runaway episodes occur at a rate of about 1.5 a week (per 55 patients). Usually these episodes occur at specific stages of treatment and provide a useful focus for interpretive work. Occasionally, significantly high rates (along with other indicators) have led us to seek out and remedy program problems to which running away was a reaction, as the authors suggested. However, out of 228 primarily high-runaway-risk adolescents whose treatment we have undertaken in the past 3 years, only 21 (9.3%) have failed to return from various runaway episodes to continue treatment with us. Many closed facilities I have known have had higher rates of elopement.

These facts support the recommendation by Drs. Miller and Burt that to keep acting-out adolescents in treatment, one relies not on secure physical custody but on their obvious capacity, however protested, to recognize and use treatment that meets their needs. Certainly the adolescents at our center who have been "voting with their feet" recognize treatment with token restraints as the least restraining alternative.

Austin, Tex.

More on Atypical Facial Pain

SIR: I read "Atypical Facial Pain as a Defense Against Psychosis" by John F. Delaney, M.D. (October 1976 issue) with interest. It is a not infrequent clinical experience to find symptoms of somatization and pain in psychotic patients. However, by emphasizing psychodynamics Dr. Delaney has tended to neglect other facets of his cases, namely, the relationship (if any) of drug abuse or withdrawal to the onset and presence of hallucinations and confusion in these patients. He also did not deal with the possibility that these cases may represent a chance association between relatively common symptom complexes, i.e., atypical facial pain and psychosis.

I would like to present a summary of a case that illustrates an association between intractable headache and psychosis (1). The patient was first admitted to a mental hospital in 1958 when he was 36 years old. He had auditory hallucinations (mainly the devil's voice) in clear consciousness, as well as persecutory delusions and ideas of reference. There was no history of alcohol or drug abuse, head injury, or encephalitis, and physical examination was normal. A diagnosis of schizophrenia was made, and the patient responded to high doses of chlorpromazine and was discharged to his father's care in 1959.

Severe headaches over the vertex were first noted during a short readmission in June 1959. His psychotic symptoms and headaches were largely unchanged on each of two further readmissions (1964 and 1972); each time he improved sufficiently on medication to be discharged.

On his last admission, the patient for the first time manifested confusion, and a history of abuse of phenacetin-containing headache powders was obtained from his brother. Urinalysis revealed blood and protein in the urine. Blood tests were as follows: sodium, 141 mEq/liter; potassium, 5.6 mEq/liter; chlorine, 102 mEq/liter; HCO_3, 18.5 mEq/liter; urea, 505 mg/100 ml; and hemoglobin, 8.9 g/100 ml.

The patient died 4 days after his admission to the hospital. The main findings at autopsy were an analgesic nephropathy and cardiomegaly. Semi-serial section of the brain stem revealed an extensive encephalitic-type lesion (glial knots, neuronal loss, and perivascular infiltration) involving the left trigeminal nucleus and extending from the main sensory nucleus to the caudal part of the spinal nucleus.

This case illustrates not only the complexity of the factors to be considered but also the morbidity and mortality that may be associated with this syndrome.

Narcolepsy and Schizophrenia

SIR: I read with great interest the article by Bruce Shapiro, M.D., and Henry Spitz, M.D., "Problems in the Differential Diagnosis of Narcolepsy Versus Schizophrenia" (November 1976 issue). At present I am treating a patient who in my opinion has both schizophrenia and narcolepsy.

The patient is a 50-year-old man who approximately 10 years ago began experiencing the sudden onset of sleep while eating, driving, or working. In several instances the sudden onset of sleep resulted in moderate injury and on at least three occasions he miraculously avoided serious injury when he fell asleep at the wheel of his automobile.

The patient has been evaluated in the past by a number of neurologists and psychiatrists who entertained the possibility of concurrent narcolepsy and depression. However, EEGs were consistently normal; a 24-hour EEG was never performed. He was placed on a trial of methylphenidate and imipramine, with only mild improvement.

An in-depth history on this patient revealed that he experiences cataplexy, sleep paralysis, and hypnogogic hallucinations. He also acknowledges the presence of auditory hallucinations. His mental status examination was noteworthy in that his affect was flat, his mood was severely dysphoric, and he was fearful that people were out to harm him. His sensory examination revealed no signs of organicity.

Psychological testing revealed a profile that best fit the category of a schizo-affective disorder. Neurological referral substantiated the earlier impressions that narcolepsy was present, although once again an EEG done in the office was unremarkable.

The patient has responded well to a combination of 150 mg/day of amitriptyline and 30 mg/day of *d*-amphetamine after trials of up to 60 mg/day of methylphenidate failed to improve his narcolepsy. However, he continues to experience auditory hallucinations, although they are somewhat less disconcerting and occur less often. The patient's *d*-amphetamine dosage is still being readjusted and the addition of antipsychotic medication is being considered.

I present this case to remind clinicians that schizophrenia and narcolepsy need not be mutually exclusive and may be present simultaneously.

KENNETH C. ULLMAN, M.D.
Washington, D.C.

Drs. Spitz and Shapiro Reply

SIR: We thank Dr. Ullman for his interest in our article and the description of the patient he is presently treating. Dr. Ullman is clearly correct in stating that narcolepsy and schizophrenia may coexist. In fact, this was documented in the article by Sours (1) that was included in the bibliography of our paper. Sours stated that "eight patients displayed schizoid personality disturbances. Ten other patients developed frank schizophrenic psychoses which required prolonged hospitalization. Three such patients had been taking Dexedrine."

It is interesting to note, however, that Dr. Ullman's patient is described as having responded well to amitriptyline and *d*-amphetamine. Both of these drugs are well known to exacerbate schizophrenic psychosis; in view of a favorable response, one must wonder whether this patient truly has a schizophrenic illness.

Perhaps this only further highlights the point made in our paper regarding the need for accuracy in formulating diagnostic criteria when faced with clinical situations in which there is major overlap of symptoms.

Betel Nut as a GABA Blocker

SIR: In a most interesting paper, "γ-Aminobutyric Acid (GABA) and the Dopamine Hypothesis of Schizophrenia" (February 1977 issue), Daniel van Kammen, M.D., pointed up the importance of examining ways of modulating the inhibitory gabergic control of the putatively overactive dopamine-containing cells of the substantia nigra in schizophrenia. The tardive dyskinesia problem makes it particularly urgent to develop new treatment methods to replace the phenothiazines and the butyrophenones. Dr. van Kammen stated that there are no known blockers of GABA uptake with sufficient specificity to warrant study. Any such agents might act in schizophrenia similarly to the way that tricyclic antidepressants work in depression by elevating the functional levels of GABA in the gabergic synaptic cleft.

Dr. van Kammen did not mention a recent paper (1) reporting just such an agent, arecaidine, the active ingredient of betel nut. Betel has been utilized in India for centuries as a "tranquilizer." For a long time it was thought that the pharmacologically active ingredient was arecoline, a muscarinic cholinergic agonist. However, the nut is chewed with lime, which hydrolyzes the arecoline to arecaidine. This is a potent blocker of GABA uptake. Thus the psychopharmacological effects of betel nut in normal people may be due to its raising effective brain GABA levels. This in turn suggests that arecaidine and related agents should be tested in schizophrenia. Betel nut chewing causes ulcers and eventually cancers of the lip and mouth, but this is almost certainly due to the excessive exposure to the lime and not to the arecaidine per se. Arecaidine itself may not cross the blood-brain barrier, but a metabolite may do so.

Birmingham, Ala.

On Diagnostic Classification

SIR: In "Mania and Schizo-Affective Disorder, Manic Type: A Comparison" (December 1976 issue) Richard Abrams, M.D., and Michael Alan Taylor, M.D., hypothesized that mania and schizo-affective disorder, manic type, were separable on the basis of the nature of the secondary

symptoms, as proposed *DSM-III* criteria suggest. They were unable to demonstrate such a distinction, probably because of marked confusion between basic signs and secondary symptoms in these criteria.

My clinical impression is that these two disorders are different psychoses that occur in different personality disorders—manic psychosis in cyclothymic personality and schizo-affective schizophrenia in hypomanic personality.

The signs of manic psychosis include: affect—absent and cynical; mood—absent and hyperenergetic; thinking—concrete and pressured; behavior—aimless and exhausting activity; defense mechanisms—wish fulfillment and hyperactivity; and judgment—impaired regarding creativity. The symptoms include: stereotyped hyperproductivity, clang associations, word salad, cyclical psychosis, stereotyped counterfeiting, and plagiarism.

The signs of schizo-affective schizophrenia include: affect—silliness, volatile swings; mood—swings from excitement to dullness; thinking—illogical and superficial; behavior—bizarre and intermittent hyperactivity; defense—global withdrawal of interest and conventionality; judgment—impaired regarding social protocol. The symptoms include bizarre cultishness, bizarre drug and alcohol abuse, bizarre imaginary companions, neologisms, and bizarre worship of youthful appearance.

I hope that if the authors reexamine their data they will find that these criteria differentiate the illnesses more successfully. They are to be lauded for investigating some of the hypotheses on which *DSM-III* will be based and demonstrating their inaccuracy. The basic definitions of signs and symptoms in *DSM-III* proposals have little resemblance to actual signs and symptoms in patients. The spokesmen for the profession would do well to bring a halt to these proposals before we are faced with a hopelessly confused statistical nightmare that bears little, if any, resemblance to psychiatric disorders as they exist clinically.

AUGUSTUS F. KINZEL, M.D.
New York, N.Y.

Drs. Abrams and Taylor Reply

SIR: Dr. Kinzel offers his clinical impression of possible differences between manic psychosis and schizo-affective schizophrenia based on a hypothesis that the conditions are derived from distinctly separate disorders of personality and manifest specific differences in patients' presentation of psychopathology.

Unfortunately, the validity of the personality disorders he describes has yet to be determined, and we are unaware of specific criteria that could be used to test his hypothesis. The individual signs and symptoms he describes are subject to the same criticism—how, for example, would one test for "bizarre cultishness," and what evidence is there for its association with schizo-affective schizophrenia?

With a little imagination, one could create any number of "syndromes" of the sort Dr. Kinzel presents; the point is to subject them to validity testing, and this we invite Dr. Kinzel to do.

The major thrust of our research findings has been the demonstration that once a patient satisfies criteria for affective disorder, the additional presence of first-rank symptoms or other "schizophrenic" features is not of critical importance. Current procedure for *DSM-III*, however, assigns preeminence to the presence of schizophrenic features, and it is this process we would like to see reversed. If our recommendation were followed, schizo-affective disorder would be included as a subgroup of affective disorder rather than schizophrenia.

Finally, Dr. Kinzel may mistakenly feel that because we have criticized one aspect of the proposed *DSM-III* criteria we are in opposition to the entire proposal. On the contrary, we feel *DSM-III* is a progressive document of major importance for American psychiatry, and we have taken the time to examine the validity of some of its assumptions in order to strengthen it.

RICHARD ABRAMS, M.D.
MICHAEL A. TAYLOR, M.D.
Chicago, Ill.

On the Psychology of Military Incompetence, *by Norman Dixon. New York, N.Y., Basic Books, 1976, 439 pp., $12.50.*

Dr. Dixon has written a rich and fascinating account of the psychology of military command. He has examined various military leaders and commanders of the past and divided them into the successful and the failed. The book attempts to document the basic attributes and the psychological makeup of the contrasting types.

Dixon defines the characteristics of military incompetence as those which involve wastage of human resources, clinging to outworn tradition, the tendency to reject or ignore unpalatable information, the tendency to underestimate the enemy, indecisiveness, obstinate persistence at a fruitless task, failure to exploit favorable situations, failure to make adequate reconnaissance, a predilection for frontal assaults, belief in brute force, the failure to make use of surprise or deception, undue readiness to find scapegoats, suppression or distortion of news from the front, and belief in such mystical forces as fate or bad luck.

The first part of the book is devoted to a rousing discussion of prime examples of military incompetence on a vast scale. The author confines himself to examples from the British Armed Forces. As a former officer in the Royal Engineers he is most familiar with his own army's past. In any case, the British Army in the nineteenth and twentieth centuries furnished classical examples of stark incompetence. Dixon describes the Crimean War, the Boer War, warfare in India, the First World War, and the Second World War battles for Singapore and Arnhem.

Criticizing British leadership in those conflicts is, of course, shooting fish in a barrel. There could not be any more outrageous examples of total incompetence than the British command in the Crimean War. In Lord Lucan, Lord Ragland, and Lord Cardigan England managed to put together in leadership posts three men utterly unfitted for the conduct of any large enterprise, let alone one operating under the exigencies of war. These feckless aristocrats have furnished the inspiration for many books and films. It would be very difficult to find in other wars quite the careless failure to grasp wartime realities that the charge of the light brigade represented. As the French said at the time, "It is magnificent but it is not war." Nor was it successful. Lord Ragland, the British Commander-in-Chief, extravagantly exemplified most of the attributes of military incompetence mentioned above.

Later in the book Dixon deals with successful military leaders, such as Nelson, Wellington, Slim, and Allenby. They, of course, receive much less mention than do their incompetent brethren. The book, after all, is about the psychology of military incompetence rather than competence. No doubt bumblers are far more interesting subjects for psychological study than are the notoriously successful.

Dixon delineates a personality profile that he believes is characteristic of incompetent militarists. The personality type is one of anal obsessionalism, lack of self-confidence, and authoritarianism. These primary qualities are displayed as outward traits of rigidity, conformity, traditionalism, anti-intellectualism, indecisiveness, and stubbornness. Traditional military organizations reinforce these personal defenses against primary anxiety by their emphasis on ritual, dogma, codes of honor, and by what the English call "bull" and the Americans call "chicken." "Bull" is petty intrusiveness about such symbolic items as the shining of belt buckles and shoes, short haircuts, and the length of fingernails. Successful leaders tend to be those who possess creativity, flexibility, high intelligence, strong self-confidence, and a lack of authoritarianism.

The author makes a good case for categorization of commanders into these groupings; however, the case remains unproven in the scientific sense. The book shares the weakness of all psychohistory. The arguments are plausible enough in the manner of the law rather than as scientifically corroborated insights. The predominant use of secondary or tertiary sources further increases one's hesitancy about the scientific validity of the author's assertions. For example, Dixon states that Field Marshal Haig, the British Commander-in-Chief on the western front in World War I, possessed "well-marked obsessive, authoritarian traits " He also states that Haig suffered from "asthma" and alleges that he had one of his worst attacks before the ill-fated Battle of Loos in 1915. The author further asserts that asthma is a psychosomatic complaint that results from repressed aggression. All of this may be correct, or it may not be. One would have to examine Haig's medical records to know whether, in fact, he really had asthma or some other respiratory disorder that in the context of 1915 medicine might have been known by the generic name of asthma. Additionally, although few would deny the role of psychic factors in the etiology of asthmatic attacks, the belief that asthma comes on only as a result of psychogenic forces is not held by those who have studied the disease well. Finally, the author would have to demonstrate that the peculiar circumstances of that particular historical moment provoked an asthmatic attack that served as a "psychosomatic outlet for surplus aggression." This is only one of the innumerable points the author makes that would be open to challenge by someone who examined the situation in a detailed, skeptical way.

There is a disjunction between the two basic sections of the book: very lively and interesting historical and personality descriptive sketches versus an accurate description of such psychological configurations as the anal or the authoritarian personality. It is in the attempt to blend these two areas that the seams show. The blending is not smooth; the transitions are abrupt, making it seem as if there is an arbitrary quality to the juxtaposition of the historical and the psychological material. The psychohistorical genre is prone to this jagged quality of format.

Nevertheless, in spite of the feeling of final doubt about the proof of the author's main thesis, the book is a marvelous Christmas fruitcake filled with all kinds of gorgeous stories and descriptions of individuals who operated at a high level

of drama, however unworthy their own talents were to cope with the vast challenges of warfare.

All who have served in the military will recognize the types described by Dr. Dixon. They exist at lower levels as well as in exalted commands. However, anyone with further experience of life would know that such types are not, by any means, confined to the military. Civil government, the world of commerce, universities, and the various medical societies have their due share of the timid, the stubborn, the authoritarian, the indecisive, the opinionated, the dogmatic, and the incompetent. One is struck, looking at high command in any organization, by the unevenness of quality. Some individuals are supremely well-fitted for posts of major responsibility. Others have characterological and intellectual defects that make one wonder how any selection process could come up with such obvious misfits. It seems to be in the nature of human organizations that it is not always possible to choose competent leaders. In the case of the wartime military, this is particularly tragic because of the wastage of lives. A bad dean can make trouble for a school of medicine and a bad chairman of the board can run a company into bankruptcy; but a bad fleet admiral or field marshal can destroy thousands of lives unnecessarily.

RANSOM J. ARTHUR, M.D.
Los Angeles, Calif.

Philosophical Dimensions of the Neuro-Medical Sciences, *edited by Stuart F. Spicker and H. Tristram Engelhardt, Jr. Lawrence, Mass., D. Reidel Publishing Co., 1976, 268 pp., $29.00.*

This is in many respects a remarkable book. It is, to begin with, a fine specimen of bookcraft, splendidly printed and well bound, making it a pleasure to handle and to read. Also, it is devoted to an esoteric theme, one that embraces and attempts to both bridge and reconcile the basic scientific assumptions on which the neuromedical sciences are founded with the philosophical issues that these assumptions engender in the "philosophically minded."

It is to be said forthwith that the attempt at the aforedescribed reconciliation is, in this instance, inspiring but not very definitive. Prof. Marjorie Grene, in her summating remarks, states, "The network of problems in which . . . we have been entangled . . . this nest of problems has certainly not produced a finished pattern of thought for neuroscientists and philosophers to follow." On the contrary, to some extent, she says, the result was "misunderstandings or just missing of minds." However, those who will trouble to read this book (and it does not offer easy reading) will also concur with Professor Grene's enthused comments: "Yet how varied, how full of content, how tantalizing are the horizons opened up by this closing session alone," and, I would add, the other sessions too.

The central and basic question at issue in this symposium was the relation of brain to mind. Is mind an "emergent of brain organization" or is mind, as Professor Grene argues, "extrinsic," while brain, as part of the body, is "intrinsic"?

In the pursuit of these issues the 17 symposium participants ranged far and wide, drawing on the motley history of neurology, phrenology, psychosurgery, hemispheric singularity and dominance, pain, and Freud. The philosophically minded brought into the fray include Descartes (both pro and con), Flourens, Fourier, Cabanis, Magendie, Hughlings Jackson, Kant, Lashley, Sherington, Kurt Goldstein, and Michael Polanyi, to name only the preeminent and at random.

As indicated in Professor Grene's cited comments, the symposium did not yield a consensus, but the published volume of its transactions offers stimulating, provocative, and in some elements distressing reading. One distressing element is the iron grip that Cartesianism, in its materialist, mechanist, and positivist commitments, exercises on the thinking of so many of the neuromedical scientists. These scientists' simplistic, naive concepts of causality are astonishing, and their dedication to the Cartesian *Méthode*, in the light of what we know of Gestalt and holism, is archaic and atavistic.

There is, pace Pythagoras, a science not only of things but of their relations. Hans Jonas argues this (and more beside) in a brilliant chapter titled "On the Power or Impotence of Subjectivity." Professor Grene, in an equally noteworthy chapter titled "Mind and Brain: The Embodied," succinctly affirms that the belief "that there *are* sensations, isolable, identifiable, single bits of consciousness out of which experience gets built is just plumb *wrong*. . . . Our everyday experience just is not made up of psychological atoms." Incidentally, Hans Jonas and Marjorie Grene are the only symposium participants who show any sympathetic understanding of Freud and of psychoanalysis. Psychiatry itself receives but scant notice, and in the main this is negative.

To summate, this is a fine, stimulating, and instructive book that deserves a place of prominence in one's reading list and library.

IAGO GALDSTON, M.D.
Brooklyn, N.Y.

The Post-Physician Era: Medicine in the Twenty-First Century, *by Jerrold S. Maxmen. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1976, 285 pp., no price listed.*

The primary objective of this startling book is to demonstrate the feasibility, inevitability, and desirability of a post-physician era. The author predicts that within the next 50 years the present physician-centered model of health care will shift first to a health team model and then to a "medic-computer" model in the twenty-first century. At that time the physician's head will be replaced by the computer, and his or her heart by a new breed of health professional called the "medic."

The present use of computers to assist in various clinical and nonclinical functions of the physician will increase in such a way that the physician will no longer be needed. History taking, physical examination, ancillary testing, diagnoses, and, with the exception of surgery, almost all treatment will be carried out entirely by the computer. The need for physicians in the twenty-first century, Maxmen argues, is therefore a myth. Logical medical decisions that require objectivity, probability concerns, and memory will be made more competently by computers than by physicians, who are described as "frequently overworked, preoccupied with the technical aspects of their jobs . . . and respected by their colleagues because of their knowledge of medicine rather than because of their sensitivity to patients" (p. 32). Indirect care functions, including research, education, and administration, will also be accomplished by computer. The medic will deal with the educational and emotional needs of patients.

The major organizational issue to be faced in establishing the medic-computer model concerns control over the health system, including priority setting, establishing standards of care, dealing with health costs, and attaining and evaluating continuity of care. Currently, the author suggests, physicians are seen as resentful of and resistant to outside qualified authorities setting standards of medical care. A solution he proposes is worth quoting because it also conveys some of the philosophy and flavor of the book:

> With the emergence of a post-physician era a government panel of experts, drawn from the nation's most qualified medical researchers, could establish high standards of clinical care, program them into the computer, and thereby minimize the problem. . . . [Then,] because an automated system of health care would collect all relevant clinical data, these government-appointed experts will possess more information to make more valid judgments than would their modern counterparts. (p. 98)

A comprehensive review of present advances in medical communication follows, including the use of interactive television, videophone, and wireless monitoring of patients' physiological processes.

In considering the emergence of the medic, the author foresees substantial changes in the education and careers of all the physician's colleagues in the present health care system. It now takes 8 years to train a medical doctor; the medic will become qualified in 18 months. The medic's training will emphasize the psychology of illness, the need for sensitivity to group processes, medical sociology, terminology, ethics, patient administration, and the technical aspects of supportive care. As the traditional medical school disappears, there will be established colleges of health science, medical management, public health, and medical investigation as well as a form of human services information center that would assist in the education of the public.

A chapter titled "Draconian Images and the New Biology" carefully reviews present and predicted issues in organ replacement, reproduction, genetic control, behavior regulations, and aging. The ethical, moral, and legal aspects of new developments in biology are clearly considered. The current complexities of these issues create a "present shock" in the reader.

There are two appendices. One considers the critical elements in future research. The other is a chronology of the future, a daring timetable that predicts interrelated developments, in parallel-step fashion, of communication and computer technology, biomedicine and therapeutics, education and occupations, and several related factors through the year 2025.

The author acknowledges in his introduction that it is a risky business to predict what the distant future can, will, or should be. The feasibility of the medic-computer model is viewed and at times extolled by the author as inevitable. The supporting facts are impressive, compelling, well written, and documented with an excellent bibliography. However, when the author reinforces the model as a desirable conclusion, I felt the uncertainty of the travelers from the yellow brick road when they confronted the wizard. The confusing advice given led them eventually to find that their own inner wisdom, love, courage, and caring were the things that mattered most in the relief of their suffering. In my opinion, Maxmen's medic-computer model does not deal enough with key human and emotional aspects of medical practice. Whether these factors can be programmed along with logic into the computer and whether the medic, as health leader, can be programmed to deal with them through a somewhat instant insight training program in 18 months are left unclear.

The computer age can help us to gain better management of direct and indirect services and to find new metaphors in psychiatry that are presently unseen. Careful attention to future programming will be required forever, lest bureaucratic red tape be merely turned into electronic pathways or practical problems in service delivery be lost in the deliberations of the government-appointed experts who would control the standards.

This book offers many points for criticism and in doing so succeeds in a most difficult task: that of reminding us that chance favors the prepared mind and that preplanning, positive action, and the creation of a constructive and more certain future is preferable to the passive denial of change beyond a 5-year period. As an important addition to the literature on change and the future it also reminds us that 1985 is, in fact, only 8 years ahead.

JAMES W. DYKENS, M.D.
Gardner, Mass.

Pitfalls in Human Research: Ten Pivotal Points, *by Theodore Xenophon Barber. New York, N.Y., Pergamon Press, 1976, 111 pp., $6.95.*

This book is a systematic, concise, and lucid analysis of major sources of fallibility in research carried out by, for, and with human beings. Bias and errors can and frequently do produce invalid conclusions. This fact is exemplified by the author's courageous and penetrating critiques of errors and invalid conclusions in recently published scientific papers. The implications for psychiatric research are profound and more than a bit sobering. The book is of great value to research psychiatrists but, most importantly, provides the practicing psychiatrist with the knowledge he or she needs to be more critical of research reports.

The first "pitfall" Barber describes is the usually implicit research paradigm—those general beliefs and methods shared by many scientists at any given time. The paradigm has a pervasive influence on all subsequent steps in the research process. It determines the choice of hypotheses, the research design, the kind of data to be collected, and how the data will be gathered, analyzed, interpreted, generalized, and published. Barber makes a convincing case for the investigator to be aware of his or her paradigm and to be more explicit about its influence on the conclusions.

The investigator's choice of research design (e.g., same-subjects design versus randomized-group design, the inclusion or exclusion of sex differences, and the choice of scales) can determine whether the investigator obtains positive, negative, or equivocal results. Failure to replicate a study can result from only a slight variation in the research design.

A third pitfall deals with the investigator's failure to write explicit step-by-step details of the procedure, which leaves latitude for experimenters to vary procedures and thus introduce bias and make replication difficult. A fourth problem is the bias introduced by the investigator's statistical procedures. One does not need to be a statistician to understand the logic of nine common ways to manipulate data to yield highly prized "significant findings." To me the chapter on the use of statistical procedures does most to improve the

practicing clinician's ability to recognize at least the more glaring deficiencies in current research reports. Barber is to be commended for his scientific critique of the data analysis procedures employed in two widely cited psychological studies. Had appropriate data analysis procedures been employed they would have produced insignificant differences rather than the "significant findings" that were reported. His recommendations, although primarily statistical, are delightfully logical and devoid of cynicism.

In chapter 5 Barber deals with the taboo subject of investigators "fudging," by which he means the *intentional* reporting of results that differ from the results obtained. This varies from downright fraud to minor but powerful enhancement of correlation values. References from past and current literature support the idea that some investigators actually fabricate or falsify their data. Barber attributes their motivations to the tremendous competition for recognition among scientists. He suggests that the motivation for honesty among scientists is roughly proportional to the probability of detection and public exposure of cheating. He concludes by suggesting that the canons of science are probably sufficient to prevent what he terms "grand scale" fraud but that in a few cases the countermotivation to fudge wins out.

The last five chapters of the book deal with possible sources of bias, error, and incorrect conclusions introduced by the experimenter. Throughout, Barber makes it clear that the investigator is responsible for the selection and conduct of experimenters and cannot ignore the possibility that they too may be fallible.

Chapter 6 convincingly documents that the experimenter's sex, age, prestige, ethnic identity, anxiety, warmth, dominance, friendliness, and hirsute adornment affect the subjects' responses on a wide variety of specific research tests. If the investigator can decide beforehand which personal attributes of the experimenter are relevant to the tests and to the subjects' responses, he or she could select experimenters who differ on these attributes. Conclusions from studies should state that results may be limited to the specific kind of experimenter(s) used in the study.

Chapter 7 deals with the failure of the experimenter to follow the research procedures. Barber reports studies which convincingly demonstrate that most experimenters using a well-constructed protocol have serious difficulties in following prescribed research procedures. Experimenters vary widely among themselves and from subject to subject, both consciously and unwittingly. It appears that careful supervision of experimenters may be necessary to reduce this serious source of error.

Chapter 8 discusses the fact that experimenters can systematically incorrectly record or sum up their subjects' responses. Misrecording is usually in the direction of the experimenter's or investigator's desired result, according to several studies.

In chapter 9 Barber discusses fudging by the experimenter, which is easier to detect than the fudging done in privacy by the investigator. He cites a variety of studies in which experimenters were found to cheat when they were observed or checked on without their being aware of it. A surprising number of experimenters altered their data to make better correlations and, in a more difficult interview procedure, actually made up data out of whole cloth. These findings are supported by post hoc statements made by a number of experimenters regarding their own fudging. Again, it is the investigator's responsibility to provide adequate supervision to minimize cheating.

In chapter 10 Barber puts to rest the popular assumption that the experimenter, through *unintentional* use of paralinguistic cues (e.g., tone of voice) and kinesthetic cues (e.g., changes in posture and facial expression), frequently influences the subjects' responses. He reviews 75 studies that attempted to demonstrate such unintentional effects. Forty percent of the studies demonstrated that experimenters' expectations did not affect the results. The results found in some studies were due to other kinds of bias. Only a few studies showed unintentional experimenter effect as the main effect or an effect in interaction with other variables.

The last chapter, "Overview and Recommendations," contains 13 recommendations that are both a challenge to scientists and a timely contribution to the scientific method. The postscript acknowledges the absence of optimism in Barber's findings but provides substantial advice for those who dare to trod the dangerous road of experimental research.

STANLEY H. ELDRED, M.D.
Belmont, Mass.

Modern Trends in Psychosomatic Medicine 3, *edited by Oscar Hill. Boston, Mass., Butterworths, 1976, 506 pp., $24.95.*

Psychosomatic medicine is alive and growing. It is becoming more visible as it emerges from the research area to the clinical. This process has been developing as the emphasis in the field has shifted from the psychodynamic-intrapsychic to the social-environmental-ecological. Also contributing to the new visibility of psychosomatic medicine are the developments in the field of electronic monitoring of physiological processes, i.e., biofeedback.

In the 1950s and 1960s investigators at the Chicago Psychoanalytic Institute, led by Franz Alexander, developed the concept that three sets of variables codetermined the development of "the seven psychosomatic diseases": a psychodynamic constellation formed early in life, the precipitating life event, and a constitutionally determined organ vulnerability.

In the 1970s such researchers as Roessler and Engel are saying that an individual's emotional and physiological responses to a given environmental stimulus are determined by the following set of variables: the nature and intensity of the stimulus; enduring characteristic, personality, and physiological traits of the patient; and the current state of the organism, i.e., the individual's physiological state at the time he or she receives the stimulus. Z.J. Lipowski opens this book with a fine overview of psychosomatic medicine, providing observations that set the stage for what is to follow.

The book covers 24 different topics contributed by an international group of authorities. The editor has tied the topics together effectively, making it possible to read one or more of the papers with a sense of satisfaction. There is something for everyone in this volume, and as I read it I began to feel that psychosomatic medicine is becoming too appealing to be left to the exclusive domain of psychiatrists.

There is a shift in emphasis in the health care field from crisis therapy to health maintenance. The individual, "the consumer," is expected to contribute more while demanding less of the physician. Dynamic psychiatry has always emphasized this. Now the emphasis is on a much broader scale. If the general physician reading this book sees it as a way of broadening his or her ability to manage a patient, he or she will also see its potential for helping the patient shift to a greater degree of preventive self-help. We cannot and will

not cope with the forces outside ourselves until we are convinced they are there. This book provides support for such awareness.

This book will have some appeal to just about every physician. The topics range from the opening chapter, "Psychosomatic Medicine: An Overview," to the closing chapter, "The Care of Bereaved Adults." I especially responded to the chapters on "Electrodermal Activity," "Psychoendocrine Relationships in Affective Disorders," Alexithymia: A View of the Psychosomatic Process," and "Hypnosis–Auto-Hypnosis in Treating Psychosomatic Illness."

Both the providing and the receiving physician in liaison psychiatry should find this book attractive. Have it on your bookshelf as a reference for your particular interests as well as for a broader awareness of the psychosomatic approach and its increasing possibilities in patient management and education of the patient in a more healthy self-management program.

PHILIP C. ROND, M.D.
Tallahassee, Fla.

The Powerholders, *by David Kipnis. Chicago, Ill., University of Chicago Press, 1976, 227 pp., $12.50.*

This small book deals with a subject that has occupied much of our interest since the Nixon administration made us realize how close we are to forgetting that ours should be a government of laws, not of men. If our leaders can, within the limits of our systems, manipulate and control us (the author calls us "target persons") it is high time we considered their motivations and the devices that can be used for this purpose.

Dr. Kipnis feels that motivation for the exercise of power may be irrational, derived from a sense of weakness, an absence of love, feelings of inferiority, or continual anxiety. On the other hand, it may be simply role behavior. This type of power motivation seems to be distinguished by the feeling of being a pawn in a situation with considerable distance from the target person and a feeling that one is only doing one's duty. This rationalization was prominent in the Nazis who conscientiously manned the ovens in the concentration camps; unfortunately, it is also a concept used by military personnel in our own country who say they were following orders and were therefore not personally responsible. The institution provides absolution for behavior that might seem unacceptable. A third type of power motivation is described as "instrumental behavior," the idea that "induction of behavior in others can be instrumental in obtaining rewards for oneself."

There is considerable discussion of the use of rewards and coercive devices, with some evidence that rewards can be elicited if there is a sufficient number of noncompliant colleagues and apple-polishing behavior thus stands out. Under these circumstances, one is tempted to wonder where the control is placed. In a slave-master relationship the slave often exerts as much "control" as the master; there is also a time-honored joke that laboratory rats feel, perhaps with some justification, that after many trials they have taught the experimenter to provide them with rewards.

It is disturbing to be reminded of Milgram's findings in an experimental situation that most persons carried out the experimenter's order to hurt another person. Kelman and Lawrence found that 67% of a cross-section of American people said that most people would follow orders and shoot "all inhabitants of a Vietnamese village . . . including old men, women and children." Further, a study by Zimbardo involving volunteers who alternated between acting as prisoners and guards revealed that the prison guards "acted in an increasingly brutal manner and . . . reported that they enjoyed the master-slave relationships that were evolving."

It is interesting to note that Kenneth B. Clark, in a presidential address to the American Psychological Association in 1972, suggested a "biochemical pacifier" that would be a required part of the diet of world leaders and "stabilize and make dominant [their] moral and ethical propensities. . . ." This is "making the world better through chemistry" in the best possible way.

The book presents an interesting array of philosophical and experimental approaches to the problem of understanding power in many of its attributes and describes an interesting gallery of power-wielding people, including Hitler, Machiavelli, and Iago.

C.H. HARDIN BRANCH, M.D.
Santa Barbara, Calif.

Children's Rights and the Mental Health Professions, *edited by Gerald P. Koocher, Ph.D. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1976, 246 pp., $17.95.*

In a series of short essays, the majority of which are written by psychologists and a few by lawyers, this book deals with four facets of children's rights in the mental health field. It raises questions about individual professional responsibility toward child clients (i.e., telling children the results of clinical evaluations) and agency or institutional responsibility (confidentiality of children's health records). It deals with the responsibility of the mental health professions in broad social issues concerning children (the role of professionals in child-custody disputes) and, finally, discusses the legal rights of children who become involved in mental health treatment or evaluation. (Should hearings be required before children can be hospitalized for mental problems?)

The essays cover a wide terrain, ranging from the ethical problems of using children as research subjects and the dangers of overdrugging "hyperactive" children to misuse of culturally biased intelligence tests and the overintervention of state agencies into family autonomy under the rubric of neglect-and-abuse laws. They touch on virtually all of the major problems in the area of children's mental health that have surfaced over the past five years. The result is a useful overview for consciousness-raising and, I think, for training purposes.

The individual chapters are, however, uneven. The critiques and conclusions sometimes seem too pat for the complexities of the issues, and the viewpoints reflected are widely disparate: the traditional helping therapist viewing his or her own profession, the skeptical mental health worker looking at the results of legal efforts to establish children's due process rights, and the disenchanted attorney attacking the medical model underpinnings of the juvenile court. Any one of the 20-odd chapters merits a book by itself (books have indeed been written about most of these topics) to probe the subject matter adequately from an experimental point of view and to survey thoughtfully the options for doing better by children.

To me, the most provocative single issue (raised in different aspects by different authors) is the pervasiveness of institutionalized obstacles to what all mental health profes-

sionals and lawyers must accept as a common goal: sensitive, individualized, protective, nonstigmatizing treatment of troubled children and families. The following examples illustrate this point:

1. Children referred for mental evaluation or treatment are often only one piece of a pathological or dysfunctional family puzzle. There is no reason to single out the child for labeling as the "sick" one. However, private and public health insurers invariably insist that individual diagnoses be made of the child's psychiatric disorder before they will pay for the treatment; family problems are noncompensable. The no-fault principle of auto insurance surely deserves consideration in mental health insurance as well.

2. Training for mental health professionals needs revamping. Several authors point out that clinicians in training are generally exposed to children as cases, not as children, and, like sentencing judges, they rarely if ever get feedback on the results of their therapy; that according to one survey only 13% of medical researchers had even one training lecture on the ethics of research with human subjects; and that courses in pharmacology rarely take the different physiologies of children into account. Then there are the perennial conflicts of training institutions: client service must vie with training opportunities in admissions, treatment choices, and even in the content of patient records. Patients' interests are in the least amount of recorded data commensurate with treatment needs, but the training needs of students include practice in recording their observations and evaluations for supervisory reaction. One answer is two sets of records—the bareboned official one for necessary inspections by third-party payers or investigators and the therapist's private working papers, which, one hopes, would be unsubpoenable.

3. Too many of the mental health professionals who deal with children in agencies, schools, and juvenile courts engage in assessment only; they bear no responsibility for linking assessments to services. Children are thus too often labeled to no avail. Packaging evaluation and treating or at least service-brokering skills in the same people or job slots seems an overdue reform.

The path of a child advocate in such institutional arrangements is a treacherous one. On the other hand, lawyers who represent children as clients have an easy time; their single-minded loyalty to the child is officially sanctioned by their profession. Mental health professionals who opt for their perception of children's rights over their employer-institution's perceived needs may be courting personal career disaster. All of us have seen such cases.

Lawyers welcome tracts like this as an admonition to mental health professionals to protect their young clients. However, while they realize full well that enlightened and sensitive professionals are more likely than lawsuits to help more troubled youngsters in the long run, lawyers also recognize that until some of these basic institutional problems are solved their own abrasive, often exacerbating presence in the mental health field must continue.

PATRICIA M. WALD
Washington, D.C.

Marital and Family Therapy, *by Ira D. Glick, M.D., and David R. Kessler, M.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1974, 172 pp., $14.00.*

Drs. Glick and Kessler have presented a well-organized and very readable introductory text in a field that has grown so rapidly in the past decade that the beginner is often unable to know how to begin to understand the concepts and practices that have emerged. They start with a clear, concise definition of the field and include just enough of a historical perspective to enable the reader to follow the developments that have occurred. They continue with a discussion of family systems and the life cycle that elucidates concepts of family interaction and tasks with important emphases on marital and parenting coalitions and a consideration of generational boundaries. They then consider dysfunctional families.

The authors include a discussion of commonly accepted myths that the beginning therapist, as well as the family, must confront and dispel if effective therapeutic work is to be done. The sections on treatment raise many important questions, such as who should be included in family therapy sessions, what therapist combinations are advantageous and disadvantageous, and what general indications and contraindications exist. The authors present an excellent overview of specific treatment strategies and then briefly but effectively tackle the difficult area of family treatment when the identified patient has a specific psychiatric diagnosis. The appendix material on the family interview will be valuable for the beginning therapist and reinforcing for those who do only a small amount of work in this area.

Glick and Kessler have provided a clearly focused and well-balanced view of an unsettled field. They communicate with the reader, using themselves as educational facilitators in the same way that they encourage the therapist to use himself or herself in the therapeutic process. They see the family therapist as an active participant, as a role model, and as an educator to the family. This book should be required reading for all beginning family therapists.

CAROL C. NADELSON, M.D.
Boston, Mass.

The Frontier of Brief Psychotherapy: An Example of the Convergence of Research and Clinical Practice, *by David H. Malan, D.M. New York, N.Y., Plenum Medical Book Co., 1976, 358 pp., $19.95.*

The frontiers of brief psychotherapy are often invaded by psychological barbarians. Fortunately for the psychotherapeutic community, Dr. Malan is a stalwart settler in that territory. His work is a firm bulwark and constitutes a major step in the effective application of well-established psychoanalytic and psychodynamic principles to this still underdeveloped but vastly important area.

The book indicates the social necessity, the theoretical foundation, and the clinical feasibility of brief psychotherapy. The accomplishments of pioneers such as Franz Alexander, Thomas French, and Michael Balint are duly acknowledged; among more recent contributions, the work of Peter Sifneos is emphasized.

Psychodynamic formulation, focal conflict, motivation for treatment, and response to interpretation must be determined quickly and accurately in order to plan whether and what kind of brief therapy should be employed. A clear discussion of these considerations is followed by the presentation of a number of cases that provide a detailed picture of the actual therapeutic interventions and patient responses. The powerful emotional forces generated in brief therapy are stunningly evident, and the therapeutic benefits follow with impressive regularity. Dr. Malan, in his even-handed way, also heeds the dangerous potentials inherent in

this very rapid, fluid, and relentless process. Errors in diagnosis, assessment of suitability, and therapeutic technique are freely—and refreshingly—acknowledged. This renders all the more persuasive the author's strong conviction that brief psychotherapy has a firm conceptual basis that can be studied, taught, and learned. The appropriateness of brief psychotherapy for selected cases is made compellingly clear throughout the book. Brief psychotherapy should not be considered the stepchild of psychiatry, reserved for the stepchildren of society.

The book is replete with clinical wisdom and conceptual stimulation; therapists of varied backgrounds and experience can find new information pertinent to their specific needs. It could serve as an excellent text for courses in psychotherapy for psychiatric residents, clinical psychology trainees, and students of psychiatric social work. For seasoned analysts and therapists, the book, especially with its follow-up reports, will serve as a touching reminder of the many patients seen for a brief time or seen on a few occasions over a long period of time whose lives were greatly enriched by a brief contact with psychotherapy. Such cases often stand out as among the most memorable and mystifying for the therapist. The mystery is reduced by this book.

The problems of this book are few. The author, and the reader, have some difficulty discriminating between a 600-hour psychoanalysis and a 6-hour psychotherapy. At times Dr. Malan seems reluctant to acknowledge that psychoanalysis and brief psychotherapy are essentially different kinds of therapy. Another point of difficulty is the author's use of data from psychotherapy clinics with which he is probably not intimately acquainted. These deficiencies are minor and should not be seriously distracting.

Dr. Malan has made a major contribution to progress in psychodynamic psychiatry by helping to expand the range of systematic psychotherapy and by making the new territory inviting and understandable to his colleagues.

JOSEPH M. NATTERSON, M.D.
Los Angeles, Calif.

New Directions in Sex Research, *edited by Eli A. Rubinstein, Richard Green, and Edward Brecher. New York, N.Y., Plenum Press, 1976, 170 pp., $19.50.*

This volume consists of the proceedings of a conference titled Sex Research: Future Directions, held at the State University of New York at Stony Brook in June 1974. The conference was planned by Stanley F. Yolles, Paul Gebhard, Richard Green, and Eli Rubinstein. The proceedings were first published in the July 1975 issue of *Archives of Sexual Behavior. New Directions in Sex Research* is a hardcover edition of this issue of the journal.

After the opening address by Dr. Yolles, 9 papers were delivered and discussed. Discussants included invited experts. Of 10 authors, only 1 is a psychiatrist, 7 have Ph.D. degrees, 1 is an obstetrician-gynecologist, and 1 is a physiatrist. Topics covered include early sex differences in the human, research strategies in sexual identity, male-female differences in sexual arousal and behavior, evaluation of treatment procedures in heterosexual dysfunction, sexuality and physical disabilities, neuroendocrinology, animal models and problems of human sexuality, research in homosexuality, changing sex roles, and comprehensive sex research centers. In addition, there are discussions of ethical issues and recommendations for future research.

On the whole, the material in this book is well presented. The editing is of high quality, and the discussions that follow each chapter are lively. Psychiatrists not already familiar with the data put forth here will enjoy becoming so. Clinicians will be stimulated not only by the content of Goy and Goldfoot's chapter on the hormonal determinants of bisexuality in lower animals but also by the way these authors think about sexual behavior. All therapists will find the sensitive work of Dr. Theodore M. Cole on spinal cord injury and sexuality of interest.

Although the Stony Brook conference was multidisciplinary, it might have been more so. Little attention was paid to integrating the facts, hypotheses, and models presented with those derived from dynamic psychiatry. Although many aspects of sexual behavior were discussed in depth, the relationship between sexual behavior and unconscious motivation in humans was not. This limitation should not be construed as a fault, however, since all conferences must have boundaries for practical reasons. Perhaps this volume will lead to others in which the movement toward interdisciplinary communication will continue.

RICHARD C. FRIEDMAN, M.D.
New York, N.Y.

From Group Dynamics to Group Psychoanalysis: Therapeutic Applications of Group Dynamic Understanding, *edited by Morton Kissen. Washington, D.C., Hemisphere Publishing Corp. (New York, N.Y., Halsted Press, John Wiley & Sons, distributor), 1976, 352 pp., $21.95.*

Any book review reflects the subjective opinions of the reviewer; despite sincere attempts to be as unbiased and objective as possible, many personal elements are involved. This book has an exciting title, a splendidly detailed bibliography, a well-conceived format divided into six major areas, and a conclusion, but it left me with an empty feeling. Why?

In many texts with a cluster of different authors there are bound to be inconsistencies in presentation, style, and ability to present thoughts lucidly. However, in this work there is a remarkable uniformity in the presentations, characterized by two significant elements: an unbelievable use of jargon, which detracts from ideas being discussed (this use not only numbed my brain with such words as "succorance," "identificatory," "elementaristic," "powerfulness," and others but made me wonder why the authors had the need to obfuscate), and a plethora of typographical errors, suggesting a lack of not only appropriate scholarship but downright poor editing. It is my opinion that an author or editor who fails to do a careful job of editing demonstrates carelessness.

Several chapters, however, require additional comments in a more positive vein. "The Work of Wilfred Bion on Groups" by Margaret J. Rioch presents an interesting and fundamental exposition of Bion's theory of group development. This is a readable and succinct paper that clarifies Bion's major themes of basic assumption and work groups. I found "The Pleasure and Reality Principles in Group Process Teaching" by Stephen A. Applebaum in the section titled Freudian Concepts Related to Group Dynamics to be a particularly good review of the dynamics of the group. This chapter is unfortunately marred by typographical errors.

The thesis in George R. Bach's chapter, "Observations on Transference and Object Relations in the Light of Group Dynamics," has as its premise the idea that "the group does *more* to and for its members than the therapist could do for

his patients alone" and elaborates carefully and lucidly on this topic. Louis R. Ormont's contribution, "Group Resistance and the Therapeutic Contract," made me wonder why it took the analyst in this particular case eight months before intervening therapeutically. The patient "opened the session in a mood of deep despair. He was discouraged about his career and homosexual liaisons. He had reached a dead end and was thinking of leaving therapy. The analyst chose this moment to approach the role of the covertly resistant members by underlining how he had been used." (This took eight months.)

A final question is why the editor did not identify the disciplines with which the various authors are associated—psychiatry, psychology, or social work. Was this a not so subtle way of saying that all health professionals are the same? In all fairness to the reader as well as to the authors, I believe appropriate recognition of the authors' fields of practice would have been helpful as well as displaying honesty.

Although it appears my negative comments outweigh the positive ones, I feel this book could serve as a useful volume for individuals undertaking group psychoanalysis. The various carefully annotated bibliographies provide a wealth of additional material.

HOWARD A. WINKLER, M.D.
Durango, Colo.

The Leader in the Group, *edited by Zanvel A. Liff, Ph.D. New York, N.Y., Jason Aronson, 1975, 315 pp., $15.00.*

This is one of a series of books derived essentially from the Postgraduate Center for Mental Health in New York City. It is dedicated to Alexander Wolf, who was clearly a leader in that he applied psychoanalytic concepts to group psychotherapy before other therapists had ventured into that field.

The first of the book's four sections consists of excerpts from the Dr. Wolf's writings that give the essence of his perspective. These set a theme carried out rather well in the other sections of the book by giving a view of group therapy from inside the head of the therapist. The volume is refreshing in its avoidance of the cookbook-style how-to-do-it enumeration of techniques in favor of providing guiding principles and concepts that give any technique a meaning and use for therapy.

Later sections of the book include the perspectives of American and a few European group psychotherapists with a psychoanalytic orientation. The approach of these authors is often personal, subjective, and even autobiographical. S.H. Foulkes and Emanuel K. Schwartz write perhaps the most informal and personal contributions. For both the book is, most unfortunately, posthumous. Since Manny Schwartz worked so closely with Al Wolf, it is especially fitting that the last entry is a memorial article by Dr. Schwartz.

Theoretical material is presented quite well in a number of articles. Jerome Kosseff produces the longest chapter and deals with the use of object-relations theory in a well-formulated summary for group therapists.

By the end of the book one gets the impression that the title did not quite fit the spirit of the book. A number of the authors in this book and especially Al Wolf show discomfort in dealing with the everyday connotations of the word "leader." If there is a point in avoiding the word "therapist," most of the authors seem more comfortable with the paradigm of parent or even coworker.

For any group therapist seriously interested in the working concepts of his or her field, this is an excellent resource.

JAY W. FIDLER, M.D.
Plainfield, N.J.

Chronically Ill and Handicapped Children: Their Management and Rehabilitation, *by Thomas L. Creer and Walter P. Christian. Champaign, Ill., Research Press Co., 1976, 183 pp. $7.95 (paper).*

In their preface the authors indicate that chronically ill children require a considerable amount of time and attention by a large number of social agents, including physicians, teachers, psychologists, nurses, social workers, and child care workers. Both authors have worked at the National Asthma Center in Denver, Colo., and have done research on social learning principles to rehabilitate chronically ill children. They give case reports of their work with asthmatic children as well as with those suffering from cerebral palsy, mental retardation, and epilepsy. They also provide clinical examples of the various forms of therapy they have used, which include respondent conditioning, operant conditioning, and weakening and extinction of response.

In their many case examples the authors emphasize the need for therapists to work with parents, with the diverse disciplines that deal with chronically ill and handicapped children, and with boards of directors of institutions for these children. They describe their own success using behavior modification, self-monitoring, relaxation training, and systematic desensitization by reciprocal inhibition; they also include 197 references to other works.

This book is highly recommended for professionals dealing with chronically ill and handicapped children.

FRANK J. CURRAN, M.D.
New York, N.Y.

Alcohol Control Policies in Public Health Perspective. Finnish Foundation for Alcohol Studies Vol. 25, *by Kettil Bruun, Griffith Edwards, Martti Lumio, Klaus Mäkelä, Lynn Pan, Robert E. Popham, Robin Room, Wolfgang Schmidt, Ole-Jørgen Skog, Pekka Sulkunen, and Esa Österberg. Helsinki, Finland, Finnish Foundation for Alcohol Studies (New Brunswick, N.J., Rutgers University Center of Alcohol Studies, distributor), 1976, 106 pp., $8.00.*

In this brief, tightly constructed, well-referenced study of public health aspects of alcohol consumption in various societies of the industrial world (primarily Europe and the Americas), the authors propose and then set out to demonstrate the following proposition: "Changes in the *overall* consumption of alcohol beverages have a bearing on the health of the people in any society. Alcohol control measures can be used to limit consumption; thus, control of alcohol availability becomes a public health issue." The method used is primarily statistical; the authors restrict themselves to a presentation of long-term physical health damages. Mental health and sociological considerations are purposely excluded, and there is no emphasis on the clinical aspects of alcoholism as a disease process. The authors are careful to point out that these exclusions are not intended to negate the significance of these areas in considerations of individual health.

As chapter builds on chapter, an impressive array of statistics buttresses the authors' conclusions. Although I have a natural suspicion of conclusions drawn from statistical evidence alone, the data used are indeed impressive and will give anyone pause for thought, even the statistical skeptic. Some of the conclusions drawn from the data are as follows:

1. Heavy users of alcohol have a substantially increased risk of morbidity and premature death.
2. The prevalence of heavy users, however defined, is directly correlated with the per capita consumption of alcohol regardless of drinking customs or other variables, such as acceptance or nonacceptance of drunkenness in a society.
3. The overall trend in alcohol consumption throughout the industrial world has shown a remarkable increase since World War II, particularly during the 1960s.
4. The degree of overall availability of alcohol has a direct effect on the general level of alcohol consumption in a society. Therefore, alcohol control measures can be used to control consumption and, by inference, morbidity and mortality.

There is little in this book to interest the clinician who deals exclusively in the diagnosis and treatment of alcoholism. However, some of the clinician's traditional beliefs are challenged by the data presented in this book. For example, according to the data the total consumption of alcohol is distributed in a population in a manner that is fairly stable from country to country. Cultural differences and social norms do not seem to result in significant differences in this distribution. Therefore, the prevalence of heavy users in any society would be directly proportional to the per capita consumption of alcohol. This would mean that countries with the highest per capita consumption, namely the wine-drinking countries of France, Italy, Portugal, Spain, and Switzerland, will have the highest prevalence of heavy users; countries that are primarily spirit- or beer-drinking, such as the United States, Sweden, and Ireland (all of which are considered to have a high percentage of alcoholism), are lower on the list.

Although the authors disclaim that they advocate stricter control policies, their implicit suggestion is that such policies would be good from a public health point of view. They mention that such controls can involve considerable costs, which may outweigh their benefits, but it seems to me that insufficient attention has been directed to the wider social consequences that have always attended extreme control measures, namely, illicit production and trade of alcohol, criminality, and the use of other substances, which occurred during Prohibition in the United States. Of course, it was not the authors' intention to stray from their limited path to focus on these other consequences. They are aware that the area of alcohol control policies can be highly controversial; they issue caveats to potential reformers as well as to others to debate the evidence objectively.

A very useful section of the book deals with the amount of alcohol consumption that is hazardous to physical health. Although no definite conclusions can be drawn from the data, it seems that the lowest level of chronic alcohol consumption that constitutes a significant hazard to health is almost certainly less than 120 g (5 ounces) of absolute alcohol per day and possibly less than 60 g.

All in all, the book is readable, interesting, challenging to some of my myths, and provides a wealth of statistical data as well as 150 references.

JOHN H. SAYERS, M.D.
Hartford, Conn.

The Scientific Study of Marihuana, *edited by Ernest L. Abel, Ph.D. Chicago, Ill., Nelson-Hall, 1976, 299 pp., $12.50.*

This volume is a collection of papers of considerable variability in content, purpose, and scientific quality and design. The 31 papers are divided into sections, each of which has an introductory comment by the editor. Except for the excerpts from "Les Paradis Artificiels" by Charles Baudelaire, written in the last century, the papers reprinted were all published between 1967 and 1972. The 4-page introduction gives an outline history of the knowledge about the use of marijuana and the recent spread of its use and effect, particularly on young individuals. In this introduction the editor states,

> The collection of scientific reports contained in this volume represents some of the most recent findings in the area of marijuana research. Hitherto, much of this material has been buried in scientific journals, generally inaccessible to the non-professional. The purpose of this book is to make some of this material available to all interested readers, laymen and professionals alike.

The introduction also states that "socially relevant questions" that cannot be feasibly or ethically studied in humans have been observed in animals while under the influence of cannabis or its derivatives. The editor recognizes that the dosage administered to subhuman species is often 100 or more times greater than that used by humans and that generalizations from such studies therefore become problematical. In concluding the introduction, the editor says,

> The topics and articles that are included here have been selected because to me, at least, they represent some of the more socially relevant approaches to cannabis research taken by various investigators. In the conduct of some of these studies, I have had a personal involvement. My selection of material may, of course, be regarded by some readers as a biased one. What is of interest or importance to one individual is not necessarily of interest or importance to another. Still I trust that my choice of material has been diverse enough so that anyone who is interested in knowing about the effects of cannabis will find at least one topic that piques his curiosity.

The topics that I found most interesting and/or most satisfactorily presented were the excerpts from Baudelaire; "Marijuana Intoxication: Common Experiences" by C.T. Tart; "Marijuana Effects: A Survey of Regular Users" by James A. Halikas, Donald W. Goodwin, and S.B. Guze; "Adverse Reactions to Marijuana" by M.H. Keeler; "Marijuana Use in Psychiatric Illness" by J.A. Halikas, Donald W. Goodwin, and S.B. Guze; and "Marijuana in Man: Three Years Later" by L.E. Hollister.

The editorial comments preceding each section summarize the effect of the reviewed articles on the editor. I did not think that the editorial comments and introduction together served adequately to synthesize a position statement regarding marijuana from a clinician's point of view. The material gathered leaves the reader with the same sense of inconclusiveness, indecision, and equivocation that has been produced by most of the recent marijuana studies, reports, and "anthologies."

Inclusion of bibliographical references with the reprinted original papers is a useful feature of this volume. In my opinion, the presentation of everyday clinical problems associat-

ed with marijuana effects is inadequate. The sophisticated student will find no new material presented in this volume. The unsophisticated lay person, however intelligent, would not derive a solid foundation of knowledge of the subject from this volume alone. This is not unusual with editorial collections of other people's work.

DOUGLAS GOLDMAN, M.D.
Cincinnati, Ohio

Lithium in Psychiatry: A Synopsis, *edited by A. Villeneuve, M.D. Quebec, Canada, Les Presses de l'Université Laval, 1976, 205 pp., $10.00 (paper).*

This collection of papers represents the proceedings of the First Canadian International Symposium on Lithium, held in May 1974. In the main, the papers are clinically oriented. Those which discuss the biochemical and physiological properties of lithium do so with an eye toward clinical implications and clues to etiology of affective illness. The thread of clinical pragmatism is evident throughout the authors' interpretations and summaries of the most careful and relevant work in lithium therapy.

Since lithium is being used for conditions ranging from hangnails to hangovers, one welcomes Mogens Schou's authoritative evaluation of its use in a wide variety of seemingly unrelated psychiatric and nonpsychiatric illnesses. His assessment of the prophylactic uses of lithium is particularly helpful. Angst and Grof's summary of the findings of a cooperative international study of the course of unipolar depressions and bipolar psychoses also helps resolve the "who" and "how long" of prophylaxis. Papers describing the psychological problems of lithium use and the instruction of patients, nurses, and primary care physicians are timely. Next to poor patient selection, inadequate education of lithium patients and front-line personnel with subsequent failure of motivation and monitoring is probably the greatest cause of lithium failure.

The most interesting paper in my opinion is Goodwin, Wehr, and Sack's summary of the studies of the action of lithium in man. These authors take the reader through a brief but remarkably clear discussion of affective disorders, giving particular attention to the information gleaned from CSF-probenecid studies.

This book is a compilation of a number of good papers; some are already dated, but all are readable and instructive. With contributors coming from different centers and discussing the same topic with basically the same emphasis, there is an unavoidable amount of duplication and repetition. For the lithium neophyte this repetition is useful; for the more experienced this book warrants perusal for areas of special interest.

CHARLES W. BOREN, M.D.
Hartford, Conn.

Hyperactivity: Research, Theory, and Action, *by Dorothea M. Ross and Sheila A. Ross. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1976, 365 pp., $18.95.*

Only unquibbling praise is deserved by a book so complete and critical in its review of the literature on hyperactivity. The two courageous women who wrote the book are mythoclastic and iconoclastic in the extreme, as the status of the subject of hyperactivity requires. They discredit the viewpoints often held by psychiatrists, pediatricians, and behavioral scientists that tend to mystify the topic of the hyperactive child. They contend, on the basis of logic and empirical study, that hyperactivity is not synonymous with minimal brain damage (MBD), and they decry the sloppy formulations that have equated hyperactivity with MBD or with major and clinically demonstrable brain damage. Very few hyperactive children, they say (correctly, according to my own experience), suffer from any soft or hard CNS disorder. That hyperactivity is a typically neurological sign or symptom is one more myth to lay to waste. Only rarely does a hyperactive child suffer from MBD; the child who does needs a specially adapted and appropriate combination of treatment modalities that have proven helpful.

Another myth that the authors go after is that hyperactivity is mainly part of the experience of the child in middle childhood, or "latency." They show that hyperactivity is an affliction of fetuses in the last trimester of gestation, infants, preschool children, adolescents, and adults as well as elementary school children. They also show that untreated or improperly treated, a hyperactive infant often goes on into adult life with the picture of hyperactivity; there are added interactional effects that help to comprise the changing picture during different ages, but the core problems persist throughout the life span.

The Rosses also discard the myth that pemoline, methylphenidate, amphetamines, and other psychic energizers have a paradoxical effect on the hyperactive person. Further, they toss overboard the idea that these energizers improve all types of learning and lament that the more useful types of human learning are not enhanced by methylphenidate and its stimulating substitutes. They hold that intentional learning is retarded when a child is given stimulants. If incidental learning (which probably constitutes 80% of all learning by a child) is diminished, the child does not overhear valuable cues and is not aware of mannerisms, vocal nuances, and social amenities unless all of these are explicitly, formally laid out. It does not facilitate a child's gracefulness, peer acceptability, formation of friendships, or self-esteem if his or her intentional learning is improved at the expense of informal, incidental social learning. Drug therapy soothes parents and teachers into thinking that all causation resides within the child and that the adults need do nothing further.

The Rosses take a jab at another popular formulation, which views hyperactivity as principally an attention deficit. They specify that in reality the problem of the hyperactive child's attention decrement is not generic and total because in some aspects of attention and attentiveness the hyperactive child is not distinguishable from the normal child. Therefore, another researchable formulation seems rejectable.

With some gusto, I felt, the authors debunk the myth of the Strauss-Lehtinen-Kephart method of teaching hyperactive children; they point out flaws in design, method, data collection, and interpretation. Their conclusions cast serious doubt on the belief that distractibility is paramount in the problems felt and shown by the hyperactive child.

In a book that surveys and critiques research with hyperactive children it is rare to find so much attention given to the children's perspective, their own ideas about their dysfunctions and remedies. Particularly touching is the authors' repeated emphasis on the possible long-range effects, not all salutary, of the psychic energizers. Long-range drug effects haunt the Food and Drug Administration and physicians less

than they haunt the children, one suspects.

With all these good things to say about authors who make so many incisive and illuminating comments about conventional shibboleths and bandwagons, I hesitate to take exception, but I do in regard to their antimedical bias. I feel they have an outspoken and familiar antimedical agenda, e.g.:

> It assigns a coordinating role to the psychologist rather than to the pediatrician on the team; it focuses on prevention at both the professional *and* parent level; and it assigns much of the responsibility for teaching behavioral control principles to the school nurse. (p. 301)

That quotation is not out of context. The authors give no sign of recognition to psychiatry or child psychiatry, put down pediatrics, and vaunt psychology for coordination and nursing for teaching of behavioral control principles.

When they stick to research, Dorothea and Sheila Ross are brilliant. Their chapter on etiology is excellent; it is so thorough that it notes every conceivable etiological circumstance, whether sensible or nonsensical, whether pertaining to genes and temperament or to food additives and fluorescent lighting. When they turn to remedial and clinical work, however, the authors lack the luster that is otherwise very much in evidence. It is as a compendium of hyperactivity research that this volume is an indispensable and vital contribution to child psychiatry.

PAUL L. ADAMS, M.D.
Louisville, Ky.

Child Abuse and Neglect: The Family and the Community, *edited by Ray E. Helfer and C. Henry Kempe. Cambridge, Mass., Ballinger Publishing Co. (J.B. Lippincott Co.), 1976, 426 pp., $20.00.*

Two earlier volumes edited by Drs. Helfer and Kempe, *The Battered Child* (1) and *Helping the Battered Child and His Family* (2), are part of the basic literature in child abuse and neglect. The present volume will become part of that literature. The title cannot describe the diversity of important information in each of the six sections of the book.

In section 1, Dysfunction in Family Interaction, Steele writes in depth on "Violence Within the Family." He describes the complex biological, psychological, social, and cultural factors involved, concluding that violence breeds violence. Kennell, Voos, and Klaus present their studies in early parent-infant bonding and emphasize the significance of bonding from pregnancy on. Helfer, McKinney, and Ruth Kempe write about the arrest of developmental processes in childhood in pathological parent-child interactions. In "Family Pathology As Seen in England," Ounsted and Lynch illustrate 18 types of family pathology and the indicated therapy.

Section 2 contains four chapters on Evaluating the Family. The first two contributions discuss in detail how the child protection team functions and how family pathology is assessed. The second two chapters deal with sexual exploitation and incest. In "Humanistic Treatment of Father-Daughter Incest," Giarretto writes from experience with more than 250 families and emphasizes distorted family homeostasis. Section 3, Family Oriented Therapy, illustrates the need for a comprehensive multimodality interdisciplinary approach. The various authors elaborate on the details of the treatment process and indicate where the pitfalls in treatment can occur. Lynch and Ounsted again give their experience with families in residential therapy in England, and Jeffery describes in detail a behavior therapy approach used in Australia to modify parents' interaction with their children.

Section 4, The Community, consists of three chapters that are clear expositions on community organization in civilian and military life. Community organization, personnel, education, administration, financing, and many other aspects of programming receive attention. This section is valuable in that the authors, all of whom have considerable experience, illustrate the complexities of community organization and the need to persevere. Section 5, The Family and the Law, consists of contributions by authors with extensive experience with the legal aspects of abuse and neglect. Brian Fraser, an attorney, writes on "The Child and His Parents: A Delicate Balance of Rights," and Judge James Delaney addresses himself to "New Concepts of the Family Court." Section 6, Early Recognition and Prevention of Potential Problems in Family Interaction, has three chapters on assessment and prediction. The studies focus on mothers during the prenatal and perinatal periods. The methodology, protocols, and results are given, with emphasis on the fact that the research must be validated. There are extensive references for each chapter at the back of the book.

This volume presents a comprehensive view of what we currently know about child abuse and neglect. A practitioner familiar with the field would find this book to be a good review with additional studies in research areas. A psychiatrist or other professional with limited or no experience in abuse and neglect could do no better than to read this book with its wealth of basic information.

Detroit, Mich.

Basic Child Psychiatry, 2nd ed., *by Philip Barker, M.B., D.P.M., D.C.H. Baltimore, Md., University Park Press, 1976, 268 pp., $14.50.*

Those familiar with the 1971 edition of Dr. Barker's primer of child psychiatry will see that he has not only brought the text up to date but also improved the presentation of most of the sections. The result is a book reflecting an even greater breadth and maturity of clinical judgment than the first edition. Dr. Barker's eclectic approach struck some reviewers in 1971 as rather bold in that he included such items as emphasis on limit setting and use of behavior modification techniques for enuresis. Clinical eclecticism has now become more acceptable in child psychiatry; Dr. Barker's balanced approach does not stand out from the accepted approaches as much today as it did in 1971.

A unique contribution in the new edition is a chapter on the legal aspects of child psychiatry, including a very nicely written description of how to examine and how to write reports on children and adolescents for the court. In this volume there is also a greater emphasis on family group therapy as well as a new chapter on mental handicaps (the new British term for the mental retardation syndromes). In the 1971

edition references to mental handicaps were scattered among several chapters.

Even though the book is for beginners it is sufficiently comprehensive to provide a certain amount of depth. The author provides some interesting and appropriate case histories as well as selected references that seem quite useful. A glossary of treatment terms is appended for those unfamiliar with medical or psychiatric terminology. A listing of selected books and journals in the field of child psychiatry that was included in the first edition has wisely been omitted because it is difficult to keep such a list up to date.

The good qualities of the first edition have been retained, including the sections on normal development, child psychiatric disorders, and methods of assessing children and their families. The language is clear; the sections on diagnostic categories are elementary. Although the sections on family therapy are an improvement over the previous edition, they present only a simplistic introduction to this area. The section on psychological testing briefly describes specific tests in both clinical and educational areas. The section on adolescence has been expanded.

The two concluding chapters on treatment and prevention of child psychiatric disorders will be most useful to the beginner in their descriptions of the many modalities of therapy. In contrast to other elementary textbooks, *Basic Child Psychiatry* is aimed at the neophyte therapist in some very fundamental ways, such as listing five principles of psychotherapy with young children (i.e., never criticizing a child, bearing in mind that children do not come for treatment of their own accord, not plunging into straight discussion of symptoms, trying to understand the child's feelings and world as he or she sees it, and, finally, remembering that limits have to be set). Similarly basic are the descriptions of casework help for the family, family group therapy, the brief section on behavior therapy, and the practical description of the use of the psychoactive drugs and anticonvulsants.

The author can be criticized for using in an elementary text the 1969 World Health Organization proposal of a "triaxial diagnostic system"; at least on this side of the Atlantic the system has not yet found wide acceptance. There are for the most part no other serious problems for the American reader who is willing to skip over specifics about the British statutes and service and delivery systems.

In general this is a worthy revision of a fundamental textbook that could be very useful to beginning medical students, social workers, pediatric residents, psychiatric residents, and beginning residents in child psychiatry.

PAUL N. GRAFFAGNINO, M.D.
Hartford, Conn.

Child Personality and Psychopathology: Current Topics, Vol. 3, *edited by Anthony Davids, Ph.D. New York, N.Y., John Wiley & Sons, 1976, 294 pp., $18.95.*

This is the third volume of papers by a number of authors on the most current material in various areas of child development. Part 1 is concerned with personality development, part 2 with sexual development, and part 3 with psychophysiological and behavior disorders.

Part 1 is composed of two interesting chapters on the changing patterns of child rearing in alternative life-styles, including divorced parents and communal living. It also has a chapter on imaginative play and pretending. In part 2 the authors discuss juvenile gender identity, masculinity and femininity during boyhood, and homosexual orientation and its antecedents. Part 3 contains a chapter on hyperactivity, a chapter on central and autonomic system function in the hyperactive syndrome with a discussion of treatment and research implications, and a chapter on the neuropsychological approach to causation, prevention, and treatment of delinquency.

Depending on the reader and how much depth he or she wishes to go into, this book varies from chapter to chapter quite markedly. The preface and introduction are written in straightforward, easily understood language, but many of the following chapters are esoteric, and one could say there are more "we don't knows" than there are proofs of what we do know. There is a good deal of neurophysiology and biochemistry and very little dynamic psychiatry; however, a great deal is being learned in these areas that we had not recognized before.

This is a book well worth reading; it can be recommended not only to those in child psychiatry but to those who treat adult patients as well. It would be a valuable source on many subjects not well known by the average psychiatrist in training.

STUART M. FINCH, M.D.
Tucson, Ariz.

Handbook of Small Group Research, 2nd ed., *by A. Paul Hare. New York, N.Y., Free Press (Macmillan Publishing Co.), 1976, 743 pp., $19.95.*

The author defines a small group as

> any number of persons engaged in interaction with each other in a single face to face meeting or series of meetings, in which each member receives some impression or perception of each other member distinct enough so that he can, either at the time or in later questioning, give some reaction to each of the others as an individual person, even though it be only to recall that the other person was present.

This is what the book is all about.

This second edition has the same goal as the first edition, published in 1962: to make available to students, researchers, and practitioners a catalogue of the field together with some suggestions of principles by which it may be organized. There are some differences between editions that add to the book, such as the addition of separate chapters on group development and social perception and suggestions for laboratory study of the history of small group research and sensitivity training. The 1,385 references to the literature from the 1962 edition are included along with an additional bibliography of relevant articles up to 1974, making a total of 6,037 references. This provides an essential resource for sociologists, psychologists, social workers, group workers, teachers, and researchers in general.

The exhaustive review of the literature is well organized in the three parts of the book. The first section considers essential tendencies of the interaction process and group structure. Here the elements of social interaction are introduced and later elaborated. This is followed by a review of the research on the process through which culture develops, persists, and changes. The next chapter considers the interaction process as group members solve problems through discussion. This emphasis is continued in chapter 4 with a

description of the phases a group passes through in its development during the course of a single meeting and over a series of meetings. The author completes his first section by outlining the details of social perception, the role system of the group, and, finally, the network of interpersonal choice.

In part 2 the author reviews some of the factors that can be varied to produce changes in the group norm, the interaction process, the role system, and the pattern of interpersonal choice. These factors are the personalities and social characteristics of members, group size, task, communication network, and leadership.

Part 3 is a summary of the literature from the point of view of productivity. The questions considered are When is a group more productive than an individual? and What are the characteristics of the most productive groups? The four appendices provide specialized information for persons involved in teaching, research, or application.

A further example of the author's thoroughness and thoughtfulness is the abundant use of diagrams and charts to help clarify and illustrate the context of this text. Hare illustrates his clear thinking and writing by neatly summarizing the essence of each chapter in a page or two. For those who wish to go farther, he provides additional references to texts and works that cover the major contributions to the chapter theme. I found that reading the summary and then the text of the chapter made the volume much easier to understand.

Although the book was not meant to be a text in group psychotherapy for the practitioner, it becomes clear from the first page on that this is a text on something as basic as anatomy, physiology, and chemistry are to the practice of medicine. Understanding the content is bound to enrich the reader because, unlike the authors of most reference texts, throughout his book Hare projects the feeling that he is dealing with people. He never loses sight of the fact that to understand the group one must understand the person. This book is a must for those involved in small group research or group therapy.

BARNEY M. DLIN, M.D.
Philadelphia, Pa.

Adolescent Coping, *by Alice E. Moriarty, Ph.D., and Povl W. Toussieng, M.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1976, 212 pp., $14.50.*

The midwest, unlike the east, is blessed with researchers on normal adolescent development. First there was Offer and now there are Moriarty and Toussieng, who report their findings in 54 adolescents who have been studied and reported on since early childhood as part of a project at the Menninger Clinic directed by Lois Barclay Murphy.

Each of the 54 subjects had a three-hour psychiatric interview and a series of psychological tests in his/her senior year of high school. The parents were not seen, and the researchers made no effort to press for data on sex.

The authors divide their subjects into two groups on the basis of whether the adolescent denied his or her sensory experience in forming a value system or used his or her sensory system to develop a value system. The former, who were in the minority of the total group, were called "censors"; these adolescents restricted their perceptions to support their value system. The latter, who were in the majority, were called "sensers"; they sought new perceptions to alter their values. These two groups differed in many ways, such as the sources of their self-respect and their object relations.

The authors caution against generalizations from their small sample, but they found that the censors tended to have controlling mothers and distant fathers, while the sensors had close relationships with their mothers and fathers, who were much involved in their upbringing (shades of Mahler's finding that fathers represent an important bridge to reality and individuation in the earlier separation-individuation phase of development).

Despite the fact that the parents raised these adolescents according to conservative standards, 70% of the adolescents adopted nontraditional views without the kind of rebellion seen in the 1960s—i.e., they changed themselves but did not find it necessary to try to change anyone or anything else. Their tolerance of differences made it unnecessary to rebel against adults.

The authors' style of writing is clear, and their many excellent quotations from the interviews really bring the adolescents and their struggles to life. The findings both complement and supplement those of Offer, who studied normal male adolescents. The limited sample—a white conservative middle-class farm community—makes generalizations difficult, however. For example, I cannot imagine an eastern urban adolescent being so uninfluenced by television as these rural subjects were. Further, it is unfortunate that the authors refrained from pressing for sexual data—is not sex the strongest force with which the adolescent must cope?

In the last chapter the authors spell out the implications of their findings for parents, teachers, and colleagues by revealing the new points of view they developed as a result of their findings. This is a surprising chapter in an otherwise sophisticated book because the authors report as new—at least to them—points of view that, to my knowledge, have been commonplace beliefs in developmental and clinical work with adolescents for at least 25 years. The following statements provide examples: "Wish for change must not automatically be viewed as being synonymous with rebellion or a wish for revolution." "Children can and will take responsibility for their own fulfillment, if given the chance." "Parents too will be better off if they seek the sources of their own fulfillment within themselves." "They respected parents and other adults who really lived up to what they believed."

How is one to explain the paradox of clinical sophistication combined with a naïve perspective? Could it be that the authors changed from censors to sensers as a result of their work? If so, it raises questions about their objectivity in using this particular axis for analysis.

JAMES F. MASTERSON, M.D.
New York, N.Y.

The Intensive Group Experience, *by Max Rosenbaum and Alvin Snadowsky. New York, N.Y., Free Press (Macmillan Publishing Co.), 1976, 205 pp., $13.95.*

From the title I expected this would be yet another textbook-sized volume about group psychotherapy. I was therefore both surprised and pleased to find a slim book consisting of five separate chapters in easily readable print. The contributions are on vastly different aspects of group dynamics, which is partially explained by the editors' stated intention of providing a "consumer's guide" to the group experience. In fact, only Rosenbaum, in the first chapter on group psychotherapy, provides the kind of professional judgment about the variety of group experiences that is promised by

the concept of a consumer guide. In general the contributions tend toward the descriptive. The authors give detailed descriptions of a type of group experience, its historical development, and specific examples from that group process but do little in the way of either critical evaluation or appraisal of how individual psychopathology is affected in each of the groups described. The reader is treated to a first-rate review of the history of the development of group psychotherapy in the first chapter. Unfortunately, this history is repeated by subsequent contributors, although in somewhat altered forms.

Although Rosenbaum's opening chapter has some of the characteristics of a guide for the potential group therapy patient or group experience consumer, the remaining chapters often take contradictory positions about various group therapies and therapists. For instance, Rosenbaum is quite skeptical about Perls and his Gestalt therapy. In contrast, Giges and Rosenfeld describe Perls as an extraordinarily gifted therapist whose contributions are at the center of the personal growth-encounter movement.

Rosenbaum ignores any consideration of the limitations of group therapy in dealing with neurotic illness. His preference for a meaningful group therapy experience based on regressive reconstructive lines ignores the ample reasons for doubting that psychoanalytically oriented psychotherapy can be conducted with any sophistication in a group setting. The recent report of Malan and associates on the results of group psychotherapy conducted along psychoanalytic lines confirms the clinical impression that such treatment may not be beneficial to any great number of patients (1).

Although the tone of this book would indicate that a large number of Americans yearn for an intensive group experience, this is certainly not confirmed by the experience of many directors of psychiatric outpatient clinics, where it is difficult to establish and maintain group programs. The resistance to entering group therapy is routinely greater than the resistance to individual treatment. This may be related to a number of factors, including a basic positive transference, which can be easily mobilized only in an individual relationship. Many patients are simply unable to conceive of groups in a positive sense or to substitute them for the transference figure of the individual therapist. Furthermore, the feeling of many patients that they require individual attention is justified by the complexity of their internal and external difficulties. One of the early rationales for group treatments, namely, the shortage of trained psychotherapists, has become a less compelling factor and may, in many locations, be a rationalization for a form of treatment that has gained its adherents rather than a reality.

The remaining four chapters of the book are concerned with groups as social phenomena rather than treatment efforts. They include material about so-called sensitivity encounters, self-awareness groups, human relations training, and communes. Rather than summarizing the contents of each of these chapters I would like to emphasize the underlying common theme that they are overly general and vague as to what functions these groups are supposed to perform. The meaning of such groups to psychiatrists involved with treatment of neuroses, borderline conditions, and psychoses is minimal. They often represent an attempt to add something, perhaps something nonessential, to an individual's life. They stand in definite contrast to individual and group treatments that attempt to recognize illness, increase the patient's awareness of its causality when possible, and encourage working through and change based on insight or modification and, when necessary, with the help of medication.

The following statement appears without any critical comment but with a note of definite approval:

> Ida Rolf developed structural integration now commonly known as rolfing in order to free habitual patterns deeply engrained in physical structure. Rolfing is a system of deep muscle manipulation and realignment. The nature of the manipulation is based on the way the rolfer reads the structure of a client's body and its relationship to the environment.

That such a basic misunderstanding of the connection between psyche and soma could be propagated, with positive comment, is distressing indeed.

The basic problem with this book is that it is at war with itself. The first chapter is a basically sound survey of various group psychotherapy techniques. The second through fifth chapters are concerned with "movements" that have more in common with religious belief systems than psychotherapy. Unfortunately, because of the chapter distribution the forces of sound clinical judgment appear to be losing during most of it. As psychiatrists, we are frequently faced with patients who are seduced into questionable group movements that promise magical changes in the form of rapid growth and flowering of extraordinary personal capacities. It is time that we recognized the distinct possibility that experiential groups may be antitherapeutic at their very core. An individual patient who seeks treatment because of personal suffering may attain such in either a group or individual setting. However, the possibility exists that individuals may be seduced away from active professional treatment by the false belief that something can be added to their personality that will relieve suffering or that the suffering itself can be cured by growth.

For the psychiatrist this book has little to offer. As a guide for the general public it leaves much to be desired. Consumers are left on their own amid an alarming number of promises from various types of group proponents. Perhaps this book should be read by professionals in the mental health field to increase their caution in recommending a group experience for those who depend on them for insight and healing.

Boston, Mass.

Le Projet Psychothérapique: De l'Activation à l'Auto-Activation, *by Mario Berta and Jean Claude Benoit. Paris, France, Denoël, 1976, 205 pp., no price listed (paper).*

The modern psychotherapist is confronted with various, sometimes mutually opposing, schools of psychotherapeutic thought. Mario Berta and Jean Claude Benoit attempt to present in this volume a unified psychotherapeutic approach that aims at integrating biological, psychological, and social approaches to the treatment of mental illness. This attempt at integration is concretized in their formulation of a new type of psychotherapy, developed by Benoit and called "psychotherapeutic activation." Berta and Benoit show in

particular in this volume the application of this approach in individuals and in the institutional setting.

The authors briefly present the personality theory underlying their approach in the introduction. This attempt at integration is certainly very commendable, but it appears to have led the authors to a rather superficial and little elaborated mix of various points of view. The basis of their theory rests on some aspects of existential psychology, with an emphasis on the style with which each individual perceives the world. The authors differentiate several dimensions of psychological perceptions that present themselves always in a bipolar way; e.g., the time dimension ranges from the past to the future. An individual becomes neurotic when he or she uses rigidly and persistently only one pole of these various bipolar dimensions. Other theoretical viewpoints included in the authors' formulation stem from systems theory and learning theory; unconscious dynamic factors and transference issues are given a minor, almost nonexistent place in their theoretical construct.

The cornerstone of the therapeutic approach derived from this theory is a continuous emphasis on the mutually stimulating activity of therapist and patient: "The therapist-patient relationship has to be an activating one, rather than like the one between an omnipotent master and his passive apprentice." The authors therefore suggest that the patient should be invited from the first session on to accept more responsibility for his or her behavior and that his or her active engagement in therapy should be requested. They advocate the further step of gradually increasing the patient's anxiety by confronting him or her in a measured way with the anxiety-creating stimulus. The ensuing reactions will break the patient's rigid, ineffective defensive systems, and alternative modes of behavior can be introduced.

There is a continuous emphasis in this book on teaching the patient more appropriate and more effective modes of behavior. Insight is deemphasized, and understanding of the patient's rigid and faulty "style" of perception is emphasized. The patient's potential to learn new behavior is to be actively stimulated to help him or her creatively find new ways of adaptation. The final goal of the authors' therapy is not a cure but the self-activation of the patient by which he or she can pursue autonomous growth with what he or she has learned during therapy.

The authors are very well aware that their psychotherapeutic approach is a departure from the traditional psychoanalytic one and that they are attempting to present an eclectic and flexible approach based on a pragmatic-pluralistic use of various active interventions. Their approach also appears to be a formulation of a brief psychotherapy and reflects the more eclectic approach of European schools of psychotherapeutic thought. In terms of relating their approach to other newer methods of psychotherapy, one could place it near Frankl's existential logotherapy or Ellis' rational emotive therapy.

In the second part of the volume Berta presents the application of the authors' approach in the individual private practice setting. He emphasizes early and complete history taking, particularly along the lines of the individual patient's psychological reactions to past traumatic events. Berta gives a central position in the diagnostic evaluation to a "test of wishes": patients are asked to imagine themselves as nonhuman objects—one they would like to be and one they would not. The symbols obtained in this fashion are used not only diagnostically but also therapeutically by confrontation with the patient. A pictorial activation is used to expose the patient in a gradual and progressive way to the aversive stimulus represented by the negative wish symbol. Diagrams, active planning of alternative modes of behavior, and various relaxation techniques are used. Another unorthodox and thought-provoking technique is what Berta calls "kinetic objectivation." This symbolic confrontation, based on karate, is a sort of shadow boxing with an imaginary enemy and usually embodies the undesirable personality trait the patient wants to get rid of. This is integrated with an appropriate psychological preparation and exploration of the patient.

In the third section of this book Benoit presents the application of the authors' approach in the institutional setting. This section is mainly an up-to-date description of modern integrated hospital and day-hospital treatment of severe mental illness, with emphasis on the multidisciplinary approach and the integration of individual psychotherapy with a therapeutic milieu. The reader will find nothing new here; one is not quite sure why this section has been included in the book.

In all, I think that this particular method of psychotherapy adds relatively little in terms of theoretical thinking to the presently used nonanalytic body of theories. Its attempt at theoretical integration is positive but not convincing. It also leaves aside important contributions of dynamic psychology. Its very positive aspects are the emphasis on the therapist's active involvement; the clarification of maladaptive, unidimensional styles of perception; and the contribution of a number of interesting specific techniques that may be used in particular situations with specific patients. These techniques could be valuable for the eclectic therapist who is interested in an active, short psychotherapy model.

Brooklyn, N.Y.

Modern Perspectives in the Psychiatric Aspects of Surgery, *edited by John G. Howells, M.D., D.P.M. New York, N.Y., Brunner/Mazel, 1976, 729 pp., $25.00.*

This book contains 36 chapters by 48 authors from 10 different countries. As one might expect, it is sporadic in quality and continuity. The purposes of the book, as stated in the editor's preface, are to provide "a contribution towards the birth of surgeon psychiatrist" and "a unique international encyclopedia in psychiatry." The first concept, the surgeon psychiatrist, is further defined as "encompassing psychic as well as surgical diagnoses, perceptive of the psychic significance of operative surgery and with an holistic approach to management procedures." The volume also seeks a greater interaction between surgical and psychiatric departments in hospitals. However, this objective is hardly likely to be accomplished by this book.

The first chapter, "The Ethical Objectives of Surgery," is openly critical of surgery and surgeons. To ask whether surgery is really necessary, to suggest that "with any luck surgery would be obsolete in 50 or 100 years," and to admonish that surgeons "must guard against using patients to prove a theory or to advance their careers" in the opening chapter can hardly be expected to whet the surgeon's appetite for what follows. It is also regrettable that of the 48 authors only 6 are surgeons. It would appear that in a book whose authors span the globe it would have been possible to find more psychologically minded surgeons.

The book's second purpose, to provide an encyclopedia of psychological problems related to surgery, is somewhat more adequately, if sporadically, fulfilled. It should be noted

at this point that this is not a book to be read from cover to cover. The repetitive exhortations to consideration and understanding in approaching the patient are well enough said, but they become tedious when encountered in chapter after chapter. On specific topics some chapters are adequately referenced reviews while others are primarily the author's experience with a particular problem.

Among those topics which I found most useful were the following: head injury (chapter 8), accident proneness (chapter 4) and accident neurosis (chapter 35), hypnosis (chapter 28), renal transplantation (chapter 18), and surgical delirium (chapter 30). Other chapters may, of course, appeal more to other readers with particular interests. By and large the depth and comprehensiveness of individual chapters are more likely to appeal to the student than to the expert in the field. A search for particular information is aided by a good index. In such a comprehensive book one shirks from suggesting additions, but chapters on the adult burned patient and on bypass surgery for obesity would have been timely.

MYRON G. SANDIFER, M.D.
Lexington, Ky.

Physiology of Aggression and Implications for Control: An Anthology of Readings, *edited by Kenneth Evan Moyer. New York, N.Y., Raven Press, 1976, 320 pp., $15.00 (paper).*

This book is a compilation of 26 articles from the periodical literature. They have been grouped in six sections: Neurosubstrates of Aggression: Some Evidence from Animals; Endocrine Substrates of Aggression: Some Evidence from Animals; Miscellaneous Studies on Animals; Neurosubstrates of Aggression: Some Evidence from Humans; Endocrine Substrates of Aggression: Some Evidence from Humans; and Physiological Control of Aggression. Each section is preceded by a brief introduction by the editor. Approximately half of the articles deal with the physiological correlates of aggression in animals and half with studies of humans.

Most of these articles were originally published after 1965; the earliest was first published in 1961. The editor notes in the general introduction that only 4 of more than 90 books published on aggression have focused primarily on physiological variables and that all 4 of these have been published since 1970. These dates reflect the relatively recent surge of social concern and scientific interest in aggression.

Of the 6 experimental studies in section 1, 4 deal with aggression in cats and 2 with aggression in rhesus monkeys. Of the 5 articles in section 2, 4 deal with aggression in rats and mice and 1 with aggression in rhesus monkeys. Of the 3 articles in section 3, 1 deals with mice, 1 with squirrel monkeys, and the third is a review article focused largely on aggression in rats and mice. The editor notes that one cannot generalize the findings on animals to man but then asserts that "although there is a wide gap between even the highest animals and man, similar biological mechanisms influence tendencies to aggression in both" (p. xiv). The key word in this quotation is "similar." Although the neural and hormonal substrates of aggression in humans may be similar to those in lower species in a very general sense, the psychiatrist reader is not likely to find much information in the first half of this book that is germane to the diagnosis and treatment of aggressive disorders of behavior in humans.

Section 4 contains 2 articles dealing with the relationship of CNS activity to aggression. The first of these, "Behavioral and Affective Responses to Brain Stimulation in Man," reports the subjective and behavioral results of the electrical stimulation of discrete regions of the subcortex, including the thalamus and limbic system. These studies were conducted with patients undergoing neurosurgery for intractable pain. The results are reported in a manner the authors themselves characterize as "anecdotal." The most striking fact about the inclusion of this article in this volume is that aggressive behavior was reported in only one of the many patients described, a patient who was stimulated in the amygdala. Later stimulation of the amygdala in the same patient did not evoke aggressive behavior. Moreover, none of the other patients stimulated in the amygdala or any other subcortical areas exhibited aggressive behavior. It is therefore difficult to understand why this article was included in this volume.

The second article in section 4 reports the results obtained when the clinical EEGs of habitually aggressive prisoners were compared with those of prisoners who had committed a single violent crime. The author concludes that 65% of the EEGs in the first group were abnormal, compared with 24% in the second group, a significant difference. He argues that this difference supports the interpretation that single acts of aggression are provoked primarily by "life situations," while repeated aggression is "endogenous" and a consequence of CNS pathology. Psychiatrists familiar with EEG interpretation may question the author's criteria for abnormality. Most important, so many types of abnormality in so many cortical leads are included in the statistical comparison that no conclusion can be drawn regarding the specific loci for the mediation of aggression in the CNS.

Section 5 reports that positive correlations exist between male sex hormones and the degree of aggressive behavior, that "a dysfunction of either the adrenal or thyroid gland results in increased irritability," that hypoglycemia is associated with a state of hyperirritability, and that stilbestrol has provided dramatic control of both "hypersexuality and irritable aggression." Although most physicians, including psychiatrists, would agree that aggressive behavior is sometimes associated with such hormonal changes, they also agree that the presence of such changes is not a sufficient condition to induce aggression. In fact, this is essentially the conclusion reached by Kreuz and Rose in an article in this volume.

Section 6 deals with efforts to treat aggressive disorders, including neurosurgical, psychotropic, and hormonal approaches. Psychiatrists with even minimal familiarity with the literature in this area will find little new in this section.

There has been a considerable amount of psychophysiological research on psychopathic and other impulsive people. This area is not represented in this volume; this is regrettable because the research of such investigators as Hare and Lykken is more rigorous methodologically than are most of the articles that have been included.

In summary, this volume contains a number of articles authored by investigators from diverse disciplines. It is difficult to identify a coherent theme even within disciplines and impossible to do so across disciplines. Psychiatrists who are entirely unfamiliar with the physiology of aggression may learn something from this heterogeneous group of articles, but if they are seriously interested in gaining information relevant to their clinical concerns they would do well to conduct their own literature search.

ROBERT ROESSLER, M.D.
Houston, Tex.

Treatment of Schizophrenia: Progress and Prospects, *edited by Louis Jolyon West, M.D., and Don E. Flinn, M.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1976, 284 pp., $22.50.*

This volume originates from a 1972 conference on the treatment of schizophrenia at the University of California, Los Angeles. Many of the contributors are internationally recognized authorities in the field. Although most of the papers are new or updated, the literature from 1974 to the present tends to be underrepresented in the references.

There are six sections. In part 1, Models of Schizophrenia, Zubin explores the concept of vulnerability to schizophrenia in an overlong, extremely complex chapter. Kety gives a brief overview of psychobiological factors, and Mandell describes "Adaptive Macromolecular Regulation of Neurotransmission in Brain." Part 2, Psychopharmacological Approaches, fails to live up to the editors' claim that it "constitute[s] a current guide to psychopharmacological treatment of schizophrenia." May's chapter is characteristically pithy and clearly written but uncharacteristically choppy and fragmented in its approach. The chapter by Jarvik and associates provides a perfunctory view of psychopharmacological treatment, including a table that provides extremely low daily dose ranges for antipsychotic drugs for psychotic inpatients (e.g., 4–15 mg a day for haloperidol [Haldol]) (p. 87). Lipton effectively debunks megavitamin therapy in his chapter, which emphasizes the therapy's total lack of scientific validation.

In part 3, Individual Psychotherapy, Arieti and Grotstein explore psychoanalytical approaches to schizophrenia but provide no scientific or statistical data to balance those found in other sections. In part 4, Small Group Approaches, Ludwig describes his fascinating work with the "buddy treatment model" and other group treatment modalities. Mosher discusses family therapy, but his most recent reference other than his own work is from 1972.

In part 5, Milieu and Social Approaches, Liberman gives an excellent overview of behavior therapy, especially token economy systems. Lofgren describes success with "small, leaderless, process-oriented" therapy for schizophrenia. Van Putten and May discuss milieu therapy, emphasizing that it is "not an adequate substitute for treatment with antipsychotic drugs, although it may add to their effects." They also discuss the toxic overstimulation of some schizophrenic patients in some lively treatment milieus with "role diffusion, parties, loud music, inability to distinguish staff from patients." They conclude that current methods of hospital milieu therapy "add little to the treatment of the ordinary schizophrenic patient once gross neglect is corrected and adequate chemotherapy is used." Bellak convincingly presents his view that community psychiatric treatment has not been a panacea for chronic schizophrenic patients.

In part 6, titled Overview, Flynn, May, and West review the literature, especially May's brilliant 1968 book (1). However, little is done to integrate the previous parts of this volume into a coherent and consistent approach. In conclusion, this book has several excellent chapters but does not provide a comprehensive overview of the treatment of schizophrenia. It may be useful as a backup and reference work, but certainly not as a substitute for such basic textbooks as the second edition of the *Comprehensive Textbook of Psychiatry* (2).

Highlights of the 130th Annual Meeting

The 130th annual meeting of the American Psychiatric Association, which focused on the theme "Professional Responsibility and Public Trust," was held in Toronto, Ont., Canada, May 2–6, 1977. The total registration was 10,612, including 4,940 members, 3,380 nonmembers (including program participants), 668 scientific exhibitors, 132 members of the press, and 1,492 spouses and families of members.

The opening session, on Monday morning, May 2, was called to order by Robert W. Gibson, M.D., 105th President of the Association. The invocation was given by Rabbi Gunther Plaut of the Holy Blossom Temple, Toronto. Official greetings were extended by John Evans, M.D., President of the University of Toronto. Dr. Gibson read special greetings from Paul V. Godfrey, Chairman of the Metropolitan Toronto Council, and from David Crombie, Mayor of the City of Toronto. Dr. Gibson then introduced Dr. S.E. Greben, Chairman of the Board of Directors, Dr. André Coté, Secretary, and Dr. John S. Pratten, President, Canadian Psychiatric Association. Dr. Pratten read a message from Prime Minister Pierre Trudeau and extended greetings on behalf of the Canadian Psychiatric Association.

Dr. Gibson introduced the distinguished guests, who included the following: Dr. Tsung-yi Lin, President of the World Federation for Mental Health; Dr. Gerald J. Sarwer-Foner, President of the American Academy of Psychiatry and the Law; Dr. John Wolfe, President of the National Council of Community Mental Health Centers; Dr. Irving N. Berlin, President of the American Academy of Child Psychiatry; Dr. Paul Chodoff, President of the American Academy of Psychoanalysis; Dr. John L. Carleton, President of the American Association for Social Psychiatry; Dr. Marc Hollender, Vice-President and representative of the American Board of Psychiatry and Neurology; Dr. George L. Lipton, the Honorable Federal Secretary and National Representative of the Australian and New Zealand College of Psychiatrists; Dr. John H. Budd, President-Elect and representative of the American Medical Association; Dr. Edward O. Harper, President of the American College of Psychiatrists; Dr. Léon Chertok, Secretary of the Société de Médecine Psychosomatique, Paris; Dr. John Donnelly, President of the National Association of Private Psychiatric Hospitals; Dr. Henry Laughlin, President of the American College of Psychoanalysts; Dr. Howard P. Rome, President of the World Psychiatric Association; Dr. Wilbert J. McKeachie, Past-President and representative of the American Psychological Association; Ms. Martha L. Mitchell, Chairperson of the American Nurses' Association's Division on Psychiatric and Mental Health Nursing Practice, representing the American Nurses' Association; Dr. Jane W. Kessler, President of the American Orthopsychiatric Association; Dr. Kenneth T. Calder, President of the American Psychoanalytic Association; Dr. Joe W. King, President-Elect and representative of the American Society for Adolescent Psychiatry; Chaplain Emanuel L. Lifschutz, President of the Association of Mental Health Clergy; Dr. Rubin L. Siegel, President of the American Society of Physician Analysts; and Dr. Walter Shervington, Chairman, Section on Neurology and Psychiatry and representative of the National Medical Association.

Dr. Gibson then called on Dr. Alfred M. Freedman, Chairperson of the Task Force To Plan a Joint Meeting with the French, who reported on plans for the meeting, to be held in Paris following the 1978 annual meeting in Atlanta. Dr. Shervert W. Frazier, Chairperson of the VI World Congress of Psychiatry Organizing Committee, commented on plans for the Congress, which will be held in Honolulu, Hawaii, August 28–Sept. 3, 1977. Dr. Tsung-yi Lin, President of the World Federation of Mental Health, extended an invitation to attend the Federation's World Congress, which will be held in Vancouver, B.C., Canada, August 21–26, 1977. The theme will be "Today's Priorities in Mental Health."

Dr. Gibson thanked Dr. Peter Martin and the Program Committee for their excellent work. Dr. Martin commented on changes in the program and noted some of its highlights. Dr. Gibson then introduced and thanked Dr. Quentin A.F. Rae-Grant, Chairperson of the Task Force on Arrangements. Following this, Dr. Frederick H. Lowy introduced a slide show prepared by the National Film Board of Canada titled "Between Friends—Entre Amis."

Vice-President Daniel X. Freedman, M.D., presented a proper accolade of Dr. Gibson, who gave an eloquent Presidential Address on "A Profession Worthy of the Public Trust." Vice-President Alan A. Stone, M.D., similarly introduced Jack Weinberg, M.D., who gave the response of the President-Elect. (The texts of these addresses are published elsewhere in this issue of the *Journal*.)

The Reverend G. Freemesser, M.D., APA Fellow and member of the Order of Basilian Fathers, St. Basil's College, Toronto, delivered the benediction. The opening session closed with organ music by John E. Fryer, M.D.

SCIENTIFIC SESSIONS

The scientific sessions began Monday afternoon, May 2. There were 429 papers presented in regular sessions, as well as 27 papers on new research presented in several sessions throughout the week. There were 150 morning and evening panels, 7 videotaped sessions, 62 courses, and 7 film sessions.

The Solomon Carter Fuller Lecture, "Black Leaders'

Handling of Their Own Anger," was given by Allison Davis, Ph.D., John Dewey Distinguished Service Professor, Department of Education, University of Chicago. David Hamburg, M.D., President of the Institute of Medicine, National Academy of Sciences, Washington, D.C., presented the Seymour Vestermark Memorial Lecture, "Reflections on Psychiatry and Medical Education in the Remainder of this Century." Professor Doctor Thure von Uexküll, Emeritus, University of Ulm, West Germany, gave the Adolph Meyer Lecture, "The Psychosomatic Approach: The Problem of a Theory of General Medicine." The Simon Bolivar Lecture, "Science and the Americas," was given by Humberto Fernandez-Moran, M.D., Professor of Biophysics, Research Institute of the University of Chicago. Daniel Aaron, Professor of American Civilization, Harvard University, Boston, Mass., was this year's Benjamin Rush Lecturer, on the subject of "The Etiquette of Grief: A Literary Generation's Response to Death."

There were 3 special lectures: "The Psychiatrist and Public Policy," by Peter G. Bourne, M.D., Special Assistant to the President for Mental Health and Drug Abuse, Washington, D.C.; "Long-Range Trends in Urban Mental Health: Old Theories and New Evidence from the Midtown Manhattan Restudy," by Leo Srole, Ph.D., Professor of Social Sciences, College of Physicians and Surgeons, Columbia University, New York, N.Y.; and "Group Cohesion and Dissidence," by J.O. Wisdom, Ph.D., University Professor of Philosophy and Social Sciences, York University, Toronto, Ont., Canada.

CONVOCATION

Dr. Gibson presided at the 21st Convocation of Fellows, held in the Grand Ballroom of the Sheraton Centre on Monday, May 2. An invocation was given by the Right Reverend H. Stiff, Dean of St. James Cathedral, Toronto. Jack Weinberg, M.D., President-Elect, then inducted Life Fellows and Fellows.

Dr. Gibson introduced Manfred Bleuler, M.D., Zurich, Switzerland, Jean Paul Delay, M.D., Paris, France, and Pierre Georges Deniker, M.D., Paris, France, who were designated Distinguished Fellows of the Association. The Reverend George C. Anderson, D.D.†, Swarthmore, Pa., and Mr. Edward F.X. Lawlor, Jr., Ambler, Pa., were designated Honorary Fellows.

Dr. Gibson introduced Life Fellows and life members who have been in the Association for 50 years (1927–1977). They are: Katherine Grace Brockman, M.D., Lacey, Wash.; Walter L. Bruetsch, M.D.†, Santa Barbara, Calif.; George Eaton Daniels, M.D., New York, N.Y.; Thomas Morton French, M.D.†, Chicago, Ill.; Daniel Patrick Griffin, M.D., Bridgeport, Conn.; Henry Harper Hart, M.D., Southbury, Conn.; Livingston Spraker Hinckley, M.D., Miami, Fla.; George Stephen Johnson, M.D., San Francisco, Calif.; Leo Kanner, M.D., Baltimore, Md.; J.H. Fernand Longpre, M.D., Florence, Mass.; William Malamud, M.D., Bloomfield, N.J.; Clyde Slocomb Marshall, M.D., Halifax, Nova Scotia, Canada; Hosea Webster McAdoo, M.D., North Little Rock, Ark.; Veronica Murphy Pennington, M.D.†, Jackson, Miss.; George Salvadore Stevenson, M.D., Red Bank, N.J.; Kenneth James Tillotson, M.D., Belmont, Mass.; and Alphonse Ralph Vonderahe, M.D., Cincinnati, Ohio.

†Deceased.

The following were designated Corresponding Fellows: Dr. Romano Antonelli, Rome, Italy; Dr. Rose Chacko, Vellore, South India; Dr. Hari Dass Chopra, Parkville, Victoria, Australia; Dr. Hanfried Helmchen, Berlin, Germany; Dr. Jean Jacques Meisch, Ettelbruck, Grand Duchy of Luxembourg; Dr. M. Sarada Menon, Madras, India; Dr. Esra Seraja Petursson, Reykjavik, Iceland.

The presentation of awards followed. Dr. Gibson presented the Distinguished Service Award—given to APA members "whose distinguished careers have ennobled the profession of psychiatry"–to Jack R. Ewalt, M.D., Director, Mental Health and Behavioral Sciences Service, Veterans Administration, Washington, D.C., and Past-President of the Association (1963–1964).

The Lester N. Hofheimer Prize for Research was presented by Joel J. Elkes, M.D., to Eric R. Kandel, M.D., Division of Neurobiology and Behavior, Department of Physiology, College of Physicians and Surgeons, Columbia University, New York, N.Y., for his distinguished contribution "to an understanding of the biological basis of behavior, with special reference to problems of neuronal plasticity and the biological correlates of learning." The Hofheimer Prize Board also extended special recognition to Donald Cohen, M.D., for his "outstanding contribution to the study of biological and psychosocial aspects of human development, with special reference to the genesis of competence, and the antecedents of psychosomatic illness," and to Robert N. Emde, M.D., Theodore J. Gaensbauer, M.D., and Robert J. Harmon, M.D., for their "distinguished contribution to the study of emotional expression in infancy, with special reference to the timing and organization of behavioral shifts."

Joseph Noshpitz, M.D., presented the Agnes Purcell McGavin Award to Viola Bernard, M.D., Chairperson, APA Council on Children, Adolescents, and Their Families, and Clinical Professor Emeritus, College of Physicians and Surgeons, Columbia University, New York, N.Y., for "outstanding contributions to the prevention of mental disorders in children."

The APA Founders Award, established in 1976 to honor members "who have made outstanding contributions as author, spokesperson and advocate in the service of the mentally ill and disabled and to the art and science of helping them," was presented by Shervert H. Frazier, M.D., to Karl A. Menninger, M.D., who was characterized as an "elder statesman of our field, foremost humanist and champion of the mentally ill and troubled, striking communicator to people in all walks of life, compassionate physician and social reformer *par excellence*."

The Robert T. Morse Writers Award, which honors "popular writers who have made major contributions to the public understanding of psychiatry over an extended period of time," was then accorded to Abigail Van Buren, "columnist, writer, and lecturer of national and international impact."

The Manfred S. Guttmacher Award was presented by Carl P. Malmquist, M.D., to: Frank W. Miller, James Carr Professor of Criminal Jurisprudence, Washington University, St. Louis, Mo.; George E. Dix, Professor of Law, University of Texas at Austin; Robert O. Dawson, Wright C. Morrow Professor of Criminal Law, University of Texas at Austin; and Raymond I. Parnas, Professor of Law, University of California at Davis, for their book, *The Mental Health Process*, published by the Foundation Press, Mineola, N.Y.

The Seymour C. Vestermark Prize Award for "outstanding contributions to undergraduate and postgraduate medical education, to continuing education, and to the edu-

cation of behavioral scientists for research" was presented by L. Douglas Lenkoski, M.D., to David A. Hamburg, M.D., President, the Institute of Medicine, National Academy of Sciences, Washington, D.C.

The District Branch Newsletter of the Year Award was presented by Robert J. Campbell III, M.D., to *The Maryland Psychiatrist*, Lino Covi, M.D., Editor. This award recognizes "the overall excellence of outstanding newsletters published by the District Branches of the Association from the standpoint of editorial content, attractiveness of format, and usefulness in furthering communication within the profession."

The Isaac Ray Award for "psychiatrists, attorneys, and judges who have made outstanding contributions to legal psychiatry" was given to Bruno Comier, M.D., Professor, Department of Psychiatry, and Director, Clinic in Forensic Psychiatry, McGill University, Montreal, Que., Canada, by Naomi Goldstein, M.D.

Dr. Gibson presented a special plaque to Henry S. Sager, M.D., for his "long-term commitment to improving relations between psychiatrists in the United States and Canada."

Following the ceremonies, Dr. Gibson introduced Dr. Anne R. Somers, Professor, Departments of Community Medicine and Family Medicine, College of Medicine and Dentistry of New Jersey-Rutgers Medical School, and Research Associate, Industrial Relations Section, Princeton University. Dr. Somers gave the William C. Menninger Memorial Convocation Lecture, "Accountability, Public Policy, and Psychiatry."

The Convocation then recessed.

BUSINESS SESSION

The business session was convened as a meeting of the Assembly of District Branches acting for the membership in receiving reports of the officers and actions of the Board of Trustees. The meeting was held Tuesday afternoon, May 3, in the Grand Ballroom of the Sheraton Centre.

Dr. Gibson asked for a moment of silence in memory of deceased Fellows and members. John D. Griffin, M.D., then read a memorial to George Herbert Stevenson, M.D., Past President of the Association (1940–1941).

Robert J. Campbell, M.D., Recorder of the Assembly, called the roll of Assembly delegates and reported that a quorum was present.

Louis F. Rittelmeyer, M.D., Chairperson, Committee of Tellers, reported the results of the election of officers and trustees and of the vote on the proposed amendments to the Constitution and By-Laws. Jules H. Masserman, M.D., was certified as President-Elect; Donald G. Langsley, M.D., as Vice-President; H. Keith H. Brodie, M.D., as Secretary; Mary Ann Bartusis, M.D., as Trustee-at-Large; Abram M. Hostetter, M.D., as Area III Trustee; and Robert A. Moore, M.D., as Area VI Trustee. The Committee of Tellers also certified the approval of amendments to the following sections of the Constitution and By-Laws: Article II; Article III; Chapter One, Section 4; Chapter 2, Section 1; Chapter 2, Section 2; Chapter 3, Section 3; Chapter 7, Section 6; and Chapter 8, Section 6. The report of the Committee was accepted.

The reports of the officers to the membership followed. Jules H. Masserman, M.D., Secretary, summarized his 33-page report, which covered principal actions of the Board of Trustees and Executive Committee from April 1976 to April 1977. Charles B. Wilkinson, M.D., followed with the Treasurer's report, Irwin N. Perr, M.D., J.D., with the report of the Speaker of the Assembly of District Branches, and Daniel A. Grabski, M.D., with the report of the Speaker-Elect. Melvin Sabshin, M.D., presented the report of the Medical Director; Dr. Gibson thanked Dr. Sabshin and the Central Office staff for their work during the year. Walter H. Wellborn, M.D., Chairperson of the Committee on Constitution and By-Laws, commented on the committee's work and reviewed the procedure for submission of petitions to amend the Constitution and By-Laws, and John R. Elpers, M.D., reported for the Membership Committee. The Assembly accepted all reports as read.

Dr. Louis Jolyon West, Chairperson of the Council on Research and Development, sensed that the Council felt that its role was changing and urged that APA undertake more research of its own along the lines of the work performed by the Task Force on ECT.

Dr. Gibson then adjourned the business session and called the annual forum to order. Topics discussed included the efforts of APA to improve the image of psychiatry with other mental health disciplines, the increase in the number of members-in-training, and problems in acquiring and transferring District Branch membership. Dr. Gibson then adjourned the annual forum.

MEETINGS OF THE BOARD OF TRUSTEES

The Board of Trustees met in regular sessions on Sunday, May 1, and Thursday, May 5. At the Thursday meeting Dr. Gibson noted that the new President, Dr. Jack Weinberg, had had to return to Chicago for health reasons. He therefore was unable to preside at the session.

ALLIED MEETINGS

The following professional associations also held meetings in Toronto during the week of May 2–6: The American Association for Social Psychiatry, the American Academy of Child Psychiatry, the American Academy of Psychiatry and the Law, the American Association of Chairmen of Departments of Psychiatry, the American College of Psychiatrists, the American College of Psychoanalysts, the American Society for Adolescent Psychiatry, the American Society for Phenomenological Psychotherapy, the Association for the Advancement of Psychotherapy, the Association of Mental Health Clergy, the Behavior Therapy and Research Society, the Eastern Psychoanalytic Association, the Navy Psychiatric Seminar, and the Society of Biological Psychiatry.

LEISURE-TIME ACTIVITIES

The Task Force on Arrangements, Co-Chaired by Quentin Rae-Grant, M.D., and May Kay Lowy, arranged interesting activities in and around Toronto, including excursions to Niagara Falls, walking tours of shopping areas and Chinatown, and visits to Toronto art galleries. Other events were a lunch in honor of the families of APA officers and tours of the Ontario Science Center. Opportunities for outdoor activities comprised tennis, fishing trips, and a golf tournament.

JULES H. MASSERMAN, M.D.
Secretary, American Psychiatric Association

The American Board of Psychiatry and Neurology

The following successfully completed the Board examination given in Seattle, Wash., Feb. 7–8, 1977.

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

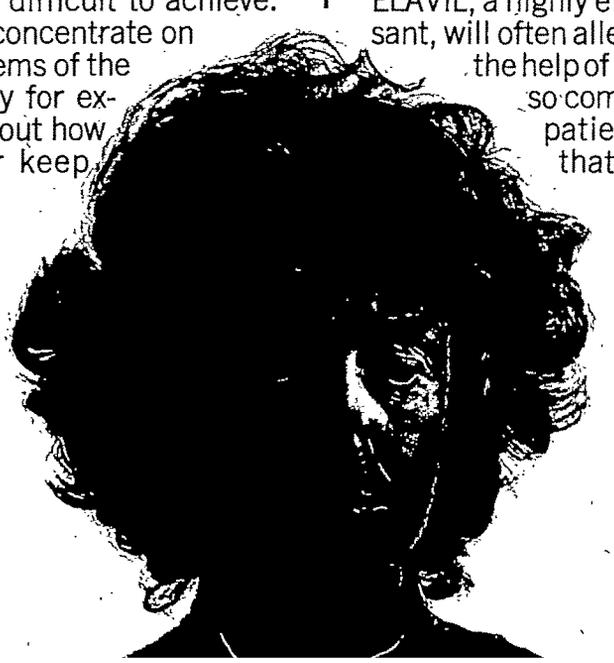
in clinically significant depression...



penetrating the symptom barrier to productive psychotherapy

symptoms often interfere with therapy

In clinically significant depression, the patient often becomes barricaded behind his own symptoms during psychotherapy. Because these symptoms can be so sharply defined and somatic in expression, he may reject the fact that they are psychic in origin. Sleep disturbance, gastrointestinal complaints, anorexia, chronic fatigue, and other psychosomatic symptoms may so preoccupy—or overwhelm—the depressed patient that truly productive therapeutic sessions are difficult to achieve. Instead of being able to concentrate on the core emotional problems of the depression itself, he may for example go on at length about how broken his sleep is or keep reiterating (while the therapeutic hour slips by) how physically miserable he feels.

ELAVIL®
(AMITRIPTYLINE HCl, MSD)
to help penetrate the symptom barrier in depression requiring medication

ELAVIL, a highly effective tricyclic antidepressant, will often alleviate these symptoms. With the help of ELAVIL, sleep disturbance—so common in clinically depressed patients and often the symptom that distresses them most—as

well as other "barrier symptoms" may be lessened to the point where they no longer come between you and the patient.

psychotherapy takes direction

As these preoccupying complaints are lifted, psychotherapy sessions can become more productive. Patients are enabled to respond more fruitfully during therapeutic hours and to resume or pursue more efficiently the necessary activities in their personal lives.

meeting therapeutic goals

And as the antidepressant activity of ELAVIL (Amitriptyline HCl, MSD) takes hold, it helps relieve the depressive condition itself. Sometimes only a minimum of actual psychotherapy is required. The patient may experience a more rapid recovery—while you conserve valuable time.

Prescribe ELAVIL then, to help lighten the patient's burden in depression—and yours in its management.

ELAVIL should not be used during the acute recovery phase following myocardial infarction; in patients hypersensitive to it; in those who have received an MAOI within two weeks; or in children under 12. Patients with cardiovascular disorders should be watched closely. Safe use during pregnancy and lactation has not been established. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Hospitalize as soon as possible any patient suspected of having taken an overdose.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
INJECTION: 10 mg per ml

ELAVIL®
(AMITRIPTYLINE HCl | MSD)
an antidepressant with an anxiety-reducing sedative component to its action

MSD
MERCK SHARP & DOHME

addendum

To further simplify once-daily therapy for many depressed patients

Tablets

ELAVIL®

(AMITRIPTYLINE HCl | MSD)

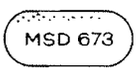
ONE TABLET, ONCE DAILY

—an appropriate way to prescribe for many depressed adult outpatients. Because of its simplicity, this regimen helps improve patient compliance. Of course, ELAVIL may also be prescribed in divided daily doses.

ONCE-DAILY DOSAGE SCHEDULE FOR ADULT OUTPATIENTS:

A single 75-mg tablet
Usual starting dosage

A single 100-mg tablet
Maximum starting dosage



A single 50-mg tablet
Minimum starting dosage

Dosage may be increased by 25 or 50 mg as necessary until a total of 150 mg per day is reached.

A single 150-mg tablet
Maximum daily dosage

ELAVIL MAY ALSO BE PRESCRIBED IN DIVIDED DAILY DOSES

The 25-mg tablet

This strength may prove useful when therapy is initiated with divided daily doses in adult outpatients. Starting dosage is usually 75 mg daily. If necessary, this dosage may be increased gradually to a total of 150 mg a day. Increases are made preferably in the late afternoon or bedtime dose.

The 10-mg tablet

This strength may prove useful for patients who require lower doses, e.g., adolescent and elderly patients. For these patients who can not tolerate higher doses, 10 mg three times a day with 20 mg at bedtime may be satisfactory.

A sedative effect may be apparent before the antidepressant effect of ELAVIL is noted. An adequate therapeutic effect may take as long as 30 days to develop.

NOTE: The usual maintenance dosage of ELAVIL is 50 to 100 mg per day which may be given in a single dose preferably at bedtime. In some patients 40 mg per day is sufficient. This drug is not recommended for patients under 12 years of age.

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.
When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

Announcing Publication . . .

MANUAL OF PSYCHIATRIC PEER REVIEW

by the Peer Review Committee of the American Psychiatric Association, Donald G. Langsley, M.D., Chairperson in cooperation with the Joint Task Force on Diagnostic Criteria for Analyzability of the American Psychoanalytic Association, William Offenkrantz, M.D., Chairperson, and the Peer Review Committee of the American Academy of Child Psychiatry. Larry B. Silver, M.D., Chairperson.

"This Manual provides a set of guidelines for district branches of APA and their peer review committees which should be adapted and modified in terms of local criteria, standards, and practices. The guidelines are not intended to be hard and fast rules. They are screening criteria, and not regulations to control practice. They are so designed that they can be utilized by non-physicians to identify those cases that can profitably be reviewed by psychiatrists serving on peer review committees. This document should be viewed as transitional, subject to revision as experience is gained, and continually updated in response to advances in psychiatric knowledge and changes in patterns of practice. . . . The application of these standards, and refinement through experience must rest with the peer review committees of district branches. . . . It should help them to move ahead in the development of a peer review for American psychiatry."

Robert W. Gibson, M.D.
President

Part I titled PSYCHIATRIC PEER REVIEW contains sections on Basic Relationships and Responsibilities, Appointment of Peer Review Committees, Funding, Operations and Procedures, Medical Care Evaluation Studies, Appeals Processes, Special Problems, Confidentiality, Educational Aspects, Medical Ethics, Advocacy, Interdisciplinary Aspects, with Appendices on Model Screening Format for Inpatient Treatment for Alcoholism, Model Screening Format for Outpatient Treatment, Sample Form for Requesting Extension of Office Treatment, Claims Review Guidelines Suggestions, APA Position Papers on Peer Review, Bibliography.

Part II titled PSYCHOANALYTIC PEER REVIEW has sections on Steps in Peer Review for Psychoanalysis, Guidelines for Model Criteria Sets, Pilot Application of Guidelines for Model Criteria Sets, Sample Peer Review Form, Sample data from Pilot Applications of Guidelines, and Glossary of Terms Used.

Part III titled PEER REVIEW AND CHILD PSYCHIATRY contains sections of Special Considerations, Legal Rights of Children, Issue of Confidentiality, Conclusions, References, and Appendices on Model Screen Criteria Format for Intermediate Care, for Acute Care in a Short Stay Facilities, and for Partial Hospitalization, Outpatient Diagnostic Evaluation Procedures, and Outpatient Treatment for Children and Adolescents.

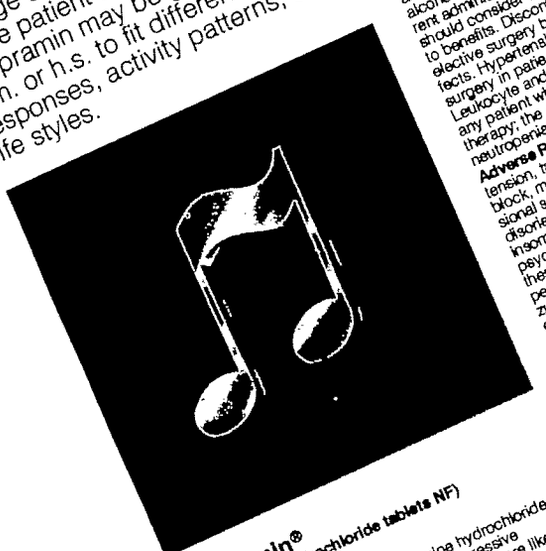
Introducing
75 mg., 100 mg., 150 mg. tablets

One tablet a day
antidepressant
with a.m. or h.s.
dosage option



Norpram
(desipramine hydrochloride)

Lightens and
brightens the days
of your depressed
patients

75 mg. tablets
100 mg. tablets
150 mg. tablets

Now Norpramin is available in 75 mg., 100 mg., and 150 mg. tablets. This means that the entire daily dosage may be given in a single tablet.

As effective as a divided dosage regimen, convenient single tablet dosage of Norpramin helps improve patient compliance. Norpramin may be given either a.m. or h.s. to fit different patient responses, activity patterns, or life styles.

Norpramin®
(desipramine hydrochloride tablets NF)

Brief Summary

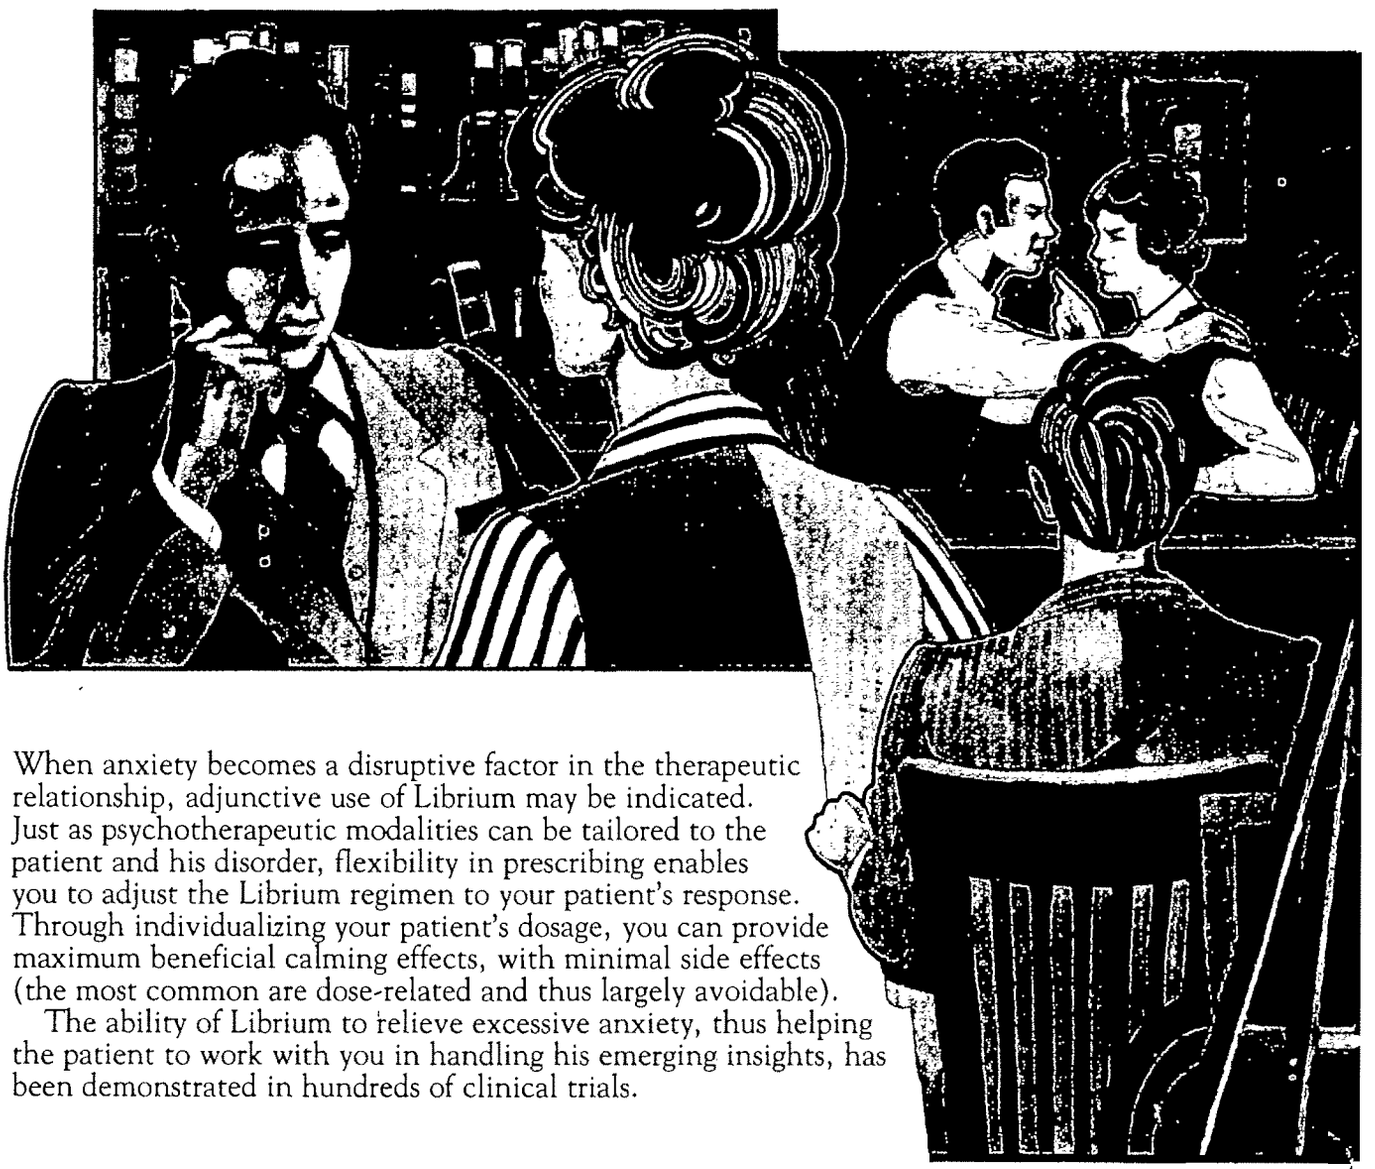
Indications: Norpramin (desipramine hydrochloride tablets NF) is indicated for the relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Desipramine hydrochloride should not be given within two weeks of treatment with a monoamine oxidase inhibitor. Contraindications include the acute recovery period following myocardial infarction and hypersensitivity to the drug. Cross sensitivity with other dibenzazepines is a possibility.

Warnings: 1. Extreme caution should be used in patients: (a) with cardiovascular disease, (b) with a history of urinary retention or glaucoma, (c) with thyroid disease or those on thyroid medication, (d) with a history of seizure disorder. 2. This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. 3. *Use in Pregnancy:* Safe use during pregnancy and lactation has not been established. 4. *Use in Children:* Norpramin is not recommended for use in children. 5. This drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. Therefore, the patient should be cautioned accordingly.

Precautions: This drug should be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with drugs of this class. If possible, dispense in child-resistant containers. It should be kept out of reach of children.–Reduce dosage, or alter treatment, if serious adverse effects occur. Norpramin therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates and may cause exacerbation of psychosis in schizophrenic patients. Use cautiously with anticholinergic or sympathomimetic drugs. Response to alcoholic beverages may be exaggerated. In the concurrent administration of ECT and antidepressant drugs one should consider the possibility of increased risk relative to benefits. Discontinue as soon as possible prior to elective surgery because of possible cardiovascular effects. Hyperpyrexia has been observed during surgery in patients on desipramine hydrochloride. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is neutropenia.

Adverse Reactions: *Cardiovascular:* hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke. *Psychiatric:* confusional states (especially in the elderly); hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis. *Neurological:* numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus. *Anticholinergic:* dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, hypotonic bladder. *Allergic:* skin rash, petechiae, urticaria, itching, photosensitization, edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs. *Hematologic:* bone marrow depressions including agranulocytosis, thrombocytopenia, purpura. *Gastrointestinal:* anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, eosinophilia, black tongue. *Endocrine:* gynecomastia, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels. *Other:* jaundice (simulating obstructive), altered liver function; weight gain or loss; perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia. *Withdrawal Symptoms:* Though not indicative of addiction, abrupt cessation after prolonged therapy may produce nausea, headache and malaise.



Dosage and Administration: *Usual adult dose:* 100 mg. to 200 mg. per day. Dosages above 200 mg. per day are not recommended. *Initial therapy:* Should be administered at a low level and increased according to tolerance and response. It may be administered in divided doses or a single daily dose. *Maintenance:* Lower adequate dose once daily to maintain remission. *Adolescent and geriatric patient dose:* 25 mg. to 100 mg. per day in single or divided doses. Dosages above 100 mg. are not recommended.

LIBRIUM® (chlordiazepoxide HCl)
ADAPTABLE TO MANY MODALITIES

When anxiety becomes a disruptive factor in the therapeutic relationship, adjunctive use of Librium may be indicated. Just as psychotherapeutic modalities can be tailored to the patient and his disorder, flexibility in prescribing enables you to adjust the Librium regimen to your patient's response. Through individualizing your patient's dosage, you can provide maximum beneficial calming effects, with minimal side effects (the most common are dose-related and thus largely avoidable).

The ability of Librium to relieve excessive anxiety, thus helping the patient to work with you in handling his emerging insights, has been demonstrated in hundreds of clinical trials.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may oc-

WHEN ANXIETY BLOCKS PROGRESS

adjunctive
LIBRIUM® IV
chlordiazepoxide HCl/Roche
THE ANXIETY-SPECIFIC

cur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

Roche announces a new psychiatric series:
"Eclecticism: The New Flexibility In Psychotherapy."

Look for it in your mail.

Roche has prepared a new series on how therapists are combining several modalities to handle different disorders. The first in this series, "A Conversation with Dr. Helen Singer Kaplan on The Eclectic Approach to Treating Sexual Dysfunction," is being mailed to psychiatrists.

a valuable link to the resources of the American Psychiatric Association

for institutions and agencies concerned with the care of the mentally disabled

Enrollment in the Hospital & Community Psychiatry Service brings multiple copies of *Hospital & Community Psychiatry* into member agencies every month, keeping staff up to date on developments and issues in the mental health field, offering new ideas and fresh perspectives, and serving as a useful resource in staff development and training programs.

Hospital & Community Psychiatry is just one of the benefits of membership in the H&CP Service. Others include a film library containing more than a hundred films specially chosen for their usefulness in staff development and community education programs; supplementary mailings of important books, reports, articles, or other material of special interest to administrators or clinicians; reduced registration fees at the annual fall Institute on Hospital & Community Psychiatry; and, on request, information and consultation from the professional staff of the American Psychiatric Association. The H&CP Service also sponsors the annual Achievement Awards competition, which gives special recognition to outstanding programs for the mentally ill and mentally retarded.

Please send me information about membership in the Hospital & Community Psychiatry Service.

INTRODUCING
NEW
SINEQUAN® 75 mg
(DOXEPIN HCl) CAPSULE

©1977, Pfizer Inc.

CLEARING OF DEPRESSION
ANTIDEPRESSANT EFFECTIVENESS...
with convenient once-a-day h.s. dosage*
SINEQUAN®
(DOXEPIN HCl)
NEW 75-mg CAPSULE
Also available:
100-mg, 50-mg, 25-mg, 10-mg CAPSULES and
ORAL CONCENTRATE 10 mg/ml, in 120-ml (4-oz) bottles
*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.
See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

IN THE TREATMENT OF CLINICAL DEPRESSION—

NEW SINEQUAN® 75 mg (DOXEPIN HCl) CAPSULE

EXTENDS THE RANGE OF DOSAGE STRENGTHS

PROVIDING ANTIDEPRESSANT EFFECTIVENESS

IN ADDITION TO OTHER, OFTEN BENEFICIAL, PROPERTIES...:

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY GOOD TOLERATION

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have occasionally been reported. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug. Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severity, a starting dose of 25 mg t.i.d. is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.

In more severely ill patients an initial dose of 50 mg t.i.d. may be required with subsequent gradual increase to 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg/day.

As an alternative regimen, the total daily dosage, up to 150 mg, may be given on a once-a-day schedule without loss of effectiveness. This dose may be given at bedtime.

Anti-anxiety effect is apparent before the antidepressant effect. Optimal antidepressant effect may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias and tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus), hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressive supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions to prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbed. The use of activated charcoal has been recommended, as has been continuous gastric lavage with saline for 24 hours or more. An adequate airway should be established in comatose patients and assisted ventilation used if necessary. EKG monitoring may be required for several days, since relapse after apparent recovery has been reported. Arrhythmias should be treated with the appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CNS symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intravenous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine is rapidly metabolized, the dosage should be repeated as required. Convulsions may respond to standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depression. Dialysis and forced diuresis generally are not of value in the management of overdosage due to high tissue and protein binding of SINEQUAN.

Supply. Available as capsules containing doxepin HCl equivalent to 10 mg, 25 mg, 50 mg, 75 mg, and 100 mg doxepin in bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). SINEQUAN 25 mg and 50 mg are also available in bottles of 5000. SINEQUAN Oral Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibrated at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Just prior to administration, SINEQUAN Oral Concentrate should be diluted with approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune or pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number of carbonated beverages. For those patients requiring antidepressant therapy who are on methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mixed together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not with grape juice. Preparation and storage of bulk dilutions is not recommended.

The Rape Victim

by Elaine Hilberman, M.D.

Mythologies about rape are legion. However, in recent years behavioral scientists have accumulated a body of information about rape and about an unfolding series of reactions experienced by the victim after rape. The aim of this concise, tightly reasoned book is to summarize what is now known about the needs and experiences of the victim and her family, and to provide a framework in which the clinician can more knowledgeably supply assistance and support. This document, published by the American Psychiatric Association, is the result of a project of the Association's Committee on Women.

Pointing out that the profound impact of rape stress is best understood in the context of rape as "a crime against the person and not the hymen," Dr. Hilberman sees rape as the ultimate violation of the self short of homicide, as an act of violence and humiliation in which not only is the victim's very existence threatened, and her inner and most private space invaded, but her autonomy and control are totally demolished. Dr. Hilberman shows that if and when the victim reports the crime, she is confronted with a complex series of yet additional stresses growing out of her contact with the hospital, police, courts, media and community opinion. Additionally, her crisis differs from other crises in that her usual social support system is likely to be disrupted. Her immediate needs are for empathy and safety, and a sense of control over what is happening in her dealings with the several agencies. Dr. Hilberman shows that in the absence of sensitivity to these needs, the experience of reporting becomes another assault.

This book presents a professional, sobering, and balanced picture of the problems of the rape victim and details what the clinician must know—about local hospital policy, criminal justice procedure, rape statutes, and community attitudes and services—in order to be able to treat victims with an understanding of the larger context in which rape occurs.

ELAINE HILBERMAN, M.D., *is in the Department of Psychiatry at the University of North Carolina School of Medicine.*

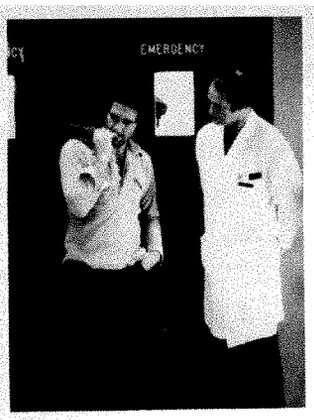
Haldol®
(haloperidol)
injection

For rapid control with minimal risk of hypotensive crises

Rapidly controls acute psychotic symptomatology[1-4] associated with: functional disorders such as schizophrenia, mania and paranoid delusional states; alcoholic withdrawal; drug abuse or withdrawal. With close patient monitoring and adequate dosage levels, initial control of symptoms has often been obtained with IM dosage in as little as one to two hours, permitting early transfer to the oral form.

Often enables you to avoid hospitalization.[5-7]
Although some instances of drowsiness have been reported, marked sedation is rare,[1,4-6] often leaving the patient ambulatory, alert and more accessible to your efforts to establish rapport.

Common side effects easily controlled.[3,5]
Although extrapyramidal symptoms (EPS) have been reported frequently, they are usually dose-related and readily controlled with dose adjustment or antiparkinson drugs. EPS often diminish spontaneously with continued use of HALDOL haloperidol.



Reduces risk of certain troublesome reactions.[1-6,8,9]
Transient hypotension occurs rarely; severe orthostatic hypotension has not been reported. Also, HALDOL haloperidol is unlikely to interact adversely with commonly abused drugs.

Can be administered at any usual I.M. site
—rarely causing additional patient discomfort[2,8] or agitation due to local irritation or stinging.

*Not an actual case history, this situation illustrates the action of HALDOL haloperidol as reported in various clinical studies (available on request).

Please turn page for information relating to Indications, Contraindications, Warnings, Precautions and Adverse Reactions.

Important: Full directions for use should be read before HALDOL haloperidol is administered or prescribed.

Haldol® (haloperidol)

tablets/concentrate/injection

For rapid control in psychiatric emergencies with minimal risk of hypotensive crises

A Dosage Form for Every Need:

5 tablet strengths for convenience in individualizing dosage: ½ mg., 1 mg., 2 mg., 5 mg. and 10 mg.

A tasteless, odorless, colorless liquid concentrate for better patient acceptability: 2 mg. per ml.

A rapid-acting injection for psychiatric emergencies: 5 mg. per ml., with 1.8 mg. methylparaben and 0.2 mg. propylparaben per ml., and lactic acid for pH adjustment to 3.4±0.2.

Indications: HALDOL haloperidol is indicated for use in the management of manifestations of psychotic disorders.

It is also indicated for the control of tics and vocal utterances of Gilles de la Tourette's syndrome.

Contraindications: HALDOL haloperidol is contraindicated in patients who are severely depressed, comatose, have CNS depression due to alcohol or other centrally-acting depressants, have Parkinson's disease or are hypersensitive to this drug.

Warnings: ***Usage in Pregnancy:*** Safe use of HALDOL haloperidol in pregnancy and lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the possible benefits of the drug be weighed against the potential hazards. A case of phocomelia in an infant whose mother received haloperidol along with a number of other medications during the first trimester of pregnancy has been reported (a causal relationship was not established in this case). Animals receiving 2 to 20 times the maximum human dose of haloperidol orally and/or parenterally showed increased incidence of resorption, reduced fertility, delayed delivery, dose-related pup mortality (presumably due to lack of maternal care reflecting CNS depression).

Usage in Children: Safety and effectiveness in children have not been established; therefore, this drug is not recommended for use in the pediatric age group.

General: Cases of bronchopneumonia, some fatal, have followed the use of major tranquilizers, including haloperidol. It has been postulated that lethargy and decreased sensation of thirst may lead to dehydration, hemoconcentration and reduced pulmonary ventilation. If these signs and symptoms appear, especially in the elderly, the physician should institute remedial therapy promptly. Although not reported with HALDOL haloperidol, decreased serum cholesterol and/or cutaneous and ocular changes have been reported in patients receiving chemically-related drugs. HALDOL haloperidol may impair the mental and/or physical abilities required for the performance of hazardous tasks such as operating machinery or driving a motor vehicle. The ambulatory patient should be warned accordingly. The use of alcohol should be avoided due to possible additive effects and hypotension.

Precautions: HALDOL haloperidol should be administered cautiously to patients: (1)—with severe cardiovascular disorders, because of the possibility of transient hypotension and/or precipitation of anginal pain. Should hypotension occur and a vasopressor be required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur. (2)—receiving anticonvulsant medication, because HALDOL haloperidol may lower the convulsive threshold. Adequate anticonvulsant therapy should be maintained concomitantly. (3)—with known allergies, or with a history of allergic reactions to drugs. (4)—receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione).

If concomitant antiparkinson medication is required, it may have to be continued after HALDOL haloperidol is discontinued because of the difference in excretion rates. If both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson agents, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used to control mania in cyclic disorders there may be a rapid mood swing to depression.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions*—Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which usually were mild to moderately severe and reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Administration of antiparkinson drugs may be required for control of such reactions. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Persistent Tardive Dyskinesia*—Tardive dyskinesia may appear during long-term therapy or after therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear irreversible. There is no known effective treatment. All antipsychotic agents should be discontinued. The syndrome may be masked by reinstitution of drug, increasing dosage, or switching to a different antipsychotic agent. *Other CNS Effects*—Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations. ***Cardiovascular Effects:*** Tachycardia and hypotension. ***Hematologic Effects:*** Reports have appeared of mild and usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis. Agranulocytosis has rarely been reported and then only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice have been reported, although a causal relationship has not been established. ***Dermatologic Reactions:*** Maculopapular and acneiform skin reactions and isolated cases of photosensitivity and loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

Complete dosage information available in insert which accompanies each package (or on request).

The use of the injectable form is intended for the acutely agitated psychotic patient with moderately severe to very severe symptoms.

IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed. 9/74

Fort Washington, Pa. 19034

Where The Action Is—

For more than a decade the general hospital psychiatric unit has been the principal locus of inpatient treatment. This latest Joint Information Service national survey brings up to date its earlier—and the original—study of this important component of the psychiatric scene. It reveals that the remarkable rate of growth held up, showing an increase of 50 percent in the number of units between 1963 and 1971, and an increase of 46 percent in the number of admissions. And it verifies that general hospital psychiatry has become increasingly comprehensive, with an impressively high level of outpatient service, emergency service, and even consultation to community agencies. Indeed, the general hospital accounts for several times as much service and activity as the widely heralded federally supported community mental health center.

This study also involves the private psychiatric hospitals, which have not changed much in number but are admitting about 10,000 more patients than in 1964—and they, too, are providing a remarkably comprehensive program.

It's your responsibility to be well-informed about these extraordinarily significant and vital pieces of American psychiatric service. You can do so by sending the order form below.

Phillip H.* was an engineer with a problem... but now he's solving problems for industry

Patient name	Phillip H.*	Sex: Male	Age: 29
Marital status S. (M.) W. D.		Occupation:	Mechanical engineer

History: Studious, bright, only son; much older sister. Father an invalid; mother, a successful business woman. A "loner" with multiple psychosomatic illnesses, he started dating late and married first girl friend, several years older

Onset of illness: Upset at wife's pregnancy, expressed strong guilt feelings after her miscarriage; said people accused him of "murder." Unable to eat or sleep properly, felt he was "losing his mind." Unable to work, obtained leave of absence and was referred to psychiatrist

Diagnosis: Acute schizophrenia

Treatment: LOXITANE® Loxapine Succinate 25 mg b.i.d. increased to 50 mg t.i.d. over 2 weeks. Supportive psychotherapy three times a week

Therapeutic course: First week, eating and sleeping better. Guilt feelings expressed less often. Mild akathisia responded to appropriate antiparkinson medication

Second week, communicating better. Feared that "fatherhood would develop into rivalry," feared loss of wife's love

Third week, no delusions or hallucinations, relating better, but still to only one person at a time

Affect still blunted at one month, otherwise asymptomatic. LOXITANE decreased to 50 mg b.i.d.; antiparkinson medication continued

Follow-up: 10 weeks; at work for one week, seems to be adjusting well. Antiparkinson medication discontinued; psychotherapy weekly, LOXITANE 25 mg t.i.d.

*Not an actual patient. The collection of clinical data upon which this simulation is built illustrates the action of LOXITANE® Loxapine Succinate as reported in clinical studies.

He's adjusting well in his job, and with psychotherapy and medication, he also can be helped to feel more secure, less threatened in his relationships with others.

See LOXITANE prescribing information on following page for indications, warnings and precautions and for more detailed information concerning side effects.

Loxitane®
LOXAPINE SUCCINATE
Lederle

For the symptoms that interrupt careers

Recommended Daily Dosage

Initial Dosage	MILD 10 mg b.i.d.	MODERATE 10 mg t.i.d. or q.i.d.	SEVERE 25 mg b.i.d.
First 7 to 10 Days	Increase dosage until psychotic symptoms are controlled. Dosage should not exceed 250 mg/day. Usual dosage during titration: 50 to 150 mg/day.		
Maintenance Dosage	Adjust to lowest effective level. Usual maintenance dosage: 60 to 100 mg/day. Many patients are controlled with dosages as low as 20 to 60 mg/day.		

Brief Summary

LOXITANE® Loxapine Succinate Capsules
OR
LOXITANE® C Loxapine Hydrochloride Oral Concentrate

Description: A dibenzoxazepine compound, representing a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines.

Indications: For the manifestations of schizophrenia. Loxapine has not been evaluated for the management of behavioral complications in mental retardation, and therefore cannot be recommended.

Contraindications: In comatose or severe, drug-induced depressed states (alcohol, barbiturates, narcotics, etc.); and in individuals with known hypersensitivity to the drug.

Warnings: In Pregnancy: Safe use during pregnancy or lactation has not been established; in pregnancy, nursing mothers, or women of child-bearing potential, weigh potential benefits against possible hazards to mother and child. No embryotoxicity or teratology was observed in studies in rats, rabbits or dogs, although with the exception of one rabbit study, the highest dosage was only two times the maximum recommended human dose and in some studies they were below this dose. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from mid-pregnancy with doses of 0.6 and 1.8 mg./kg., doses which approximate the usual human dose but which are considerably below the maximum recommended human dose. **In Children:** Studies have not been performed in children; therefore this drug is not for use below the age of 16.

May impair mental and/or physical abilities, especially during the first few days of therapy; warn ambulatory patients about activities requiring alertness (e.g., operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

Precautions: Use with extreme caution in patients with history of convulsive disorders; seizures have been reported in epileptics receiving this drug at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy. Has an antiemetic effect in animals; this effect in man may mask signs of overdosage of toxic drugs and obscure conditions such as intestinal obstruction and brain tumor. Use with caution in patients with cardiovascular disease. Increased pulse rates in the majority of patients receiving antipsychotic doses and transient hypotension have been reported. In hypotension requiring vasopressor therapy, preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine. Possibility of ocular toxicity from loxapine cannot be excluded at this time, therefore observe carefully for pigmentary retinopathy and lenticular pigmentation (observed in some patients receiving certain other antipsychotic drugs for prolonged periods). Because of possible anticholinergic action, use with caution in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinson medication.

Adverse Reactions: CNS: Adverse effects other than extrapyramidal, infrequent. Drowsiness, usually mild, may occur at beginning of therapy or when dosage is increased, usually subsiding with continued therapy. Incidence of sedation is less than that of certain aliphatic phenothiazines and slightly more than piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported. Extrapyramidal reactions during use of this drug have been reported frequently, often during the first few days of treatment. In most patients, these involve Parkinson-like symptoms such as tremor, rigidity, excessive salivation, masked facies, akathisia, usually not severe and controlled by dosage reduction or use of antiparkinson drugs in usual dosage. *Less frequent, but more severe:* Dystonias, including spasms of muscles of neck and face, tongue protrusion, oculogyric movement; dyskinesia in the form of choreo-athetoid movements. These sometimes require reduction or temporary withdrawal of drug dosage in addition to appropriate counteractive drugs. *Persistent Tardive Dyskinesia:* May appear in some patients on long-term therapy, or after therapy has been discontinued; the risk greater in the elderly, especially females, on high dosage. These symptoms, persistent and in some patients apparently irreversible, are characterized by rhythmical involuntary movement of tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements, sometimes accompanied by involuntary movements of extremities). No known effective treatment; discontinue all antipsychotic agents if these symptoms appear. The necessity to reinstitute treatment or increase dosage, or switch to a different antipsychotic agent, may mask syndrome. If medication is stopped when fine vermicular movements of the tongue occur, the syndrome may not develop. *Cardiovascular:* Tachycardia, hypotension, hypertension, lightheadedness, syncope. A few cases of EKG changes similar to those seen with phenothiazines have been reported, not known to be related to loxapine use. *Skin:* Dermatitis, edema (puffiness of face), pruritus, seborrhea. Possible photosensitivity and/or phototoxicity; skin rashes of uncertain etiology seen in a few patients during hot summer months. *Anticholinergic:* Dry mouth, nasal congestion, constipation, blurred vision—more likely to occur with concomitant use of antiparkinson agents. *Other:* Nausea, vomiting, weight gain or loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, polydipsia. Rarely, galactorrhea and menstrual irregularity of uncertain etiology.

Dosage and Administration: Administered orally, usually in 2 to 4 divided doses a day. Adjust dosage to patient's need relative to severity of symptoms and history of response to antipsychotic drugs. Recommended initial dosage is 10 mg. b.i.d.; in severely disturbed patients up to 50 mg. daily. Increase dosage during first 7 to 10 days until psychotic symptoms are controlled. Usual therapeutic and maintenance range is 60 mg.-100 mg. daily. More than 250 mg. daily is not recommended. Maintenance dosage should be at lowest level to control symptoms; many patients have been maintained on 20 mg. to 60 mg. daily.

LOXITANE C Oral Concentrate should be mixed with orange and grapefruit juice shortly before administration. Use only enclosed calibrated dropper.

Coverage and Utilization of Care for Mental Conditions Under Health Insurance —Various Studies, 1973–74

By Louis S. Reed, Ph.D.
Consultant in Health Economics, American Psychiatric Association

This book reports six studies that add to the growing body of data demonstrating the feasibility of covering mental illness under health insurance. Although in some ways it may be considered a supplement to APA's 1972 book **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (Reed, Myers, and Scheidemandel), all of the data are new. The studies cover the following areas:

- Utilization of mental benefits under the Blue Cross and Blue Shield plan for federal employees, documenting that a "plateau" in the use of these benefits was reached in 1973–74.
- Comparison of benefits for mental and other illnesses under selected employee health benefit plans.
- Coverage of mental illness under collective bargaining agreements of selected unions.
- Utilization of care for mental conditions under the Canadian health insurance program, which gives the same coverage for mental as for other conditions.
- Updating of information on Blue Cross benefits for hospital care of mental illness.
- Data from selected Blue Cross and Blue Shield plans on coverage and utilization of mental conditions, with emphasis on major medical coverage.

80pp. Paperbound

Single copy, $4.00; 10–49 copies; $3.80 each; 50 or more copies, $3.20 each.

SPECIAL OFFER: One copy of this book (regular price, $4.00) and one copy of **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (regular price, $6.50) for $8.50.

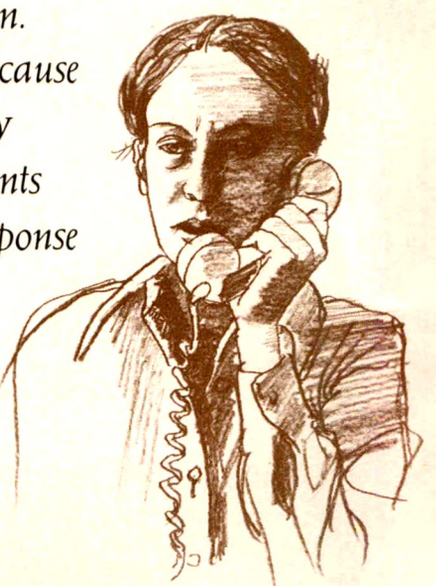
Why Endep® makes with amitriptyline HCl

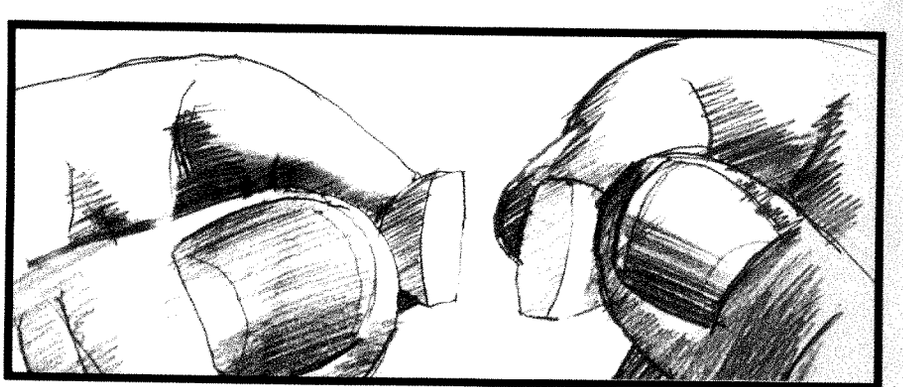


Hypothetical 30-day course of Endep therapy for a 120 lb., 35-year old woman.

Half-dose adjustments h.s., depending on progress or side effects.

Because therapeutic levels of amitriptyline vary greatly from patient to patient, reaching the optimal dose requires careful titration. Endep (amitriptyline HCl) greatly facilitates this process because it is the only tricyclic with which you can adjust dosage by half-tablet increments or decrements according to the therapeutic response and/or side effects.

ROCHE



titration more practical:

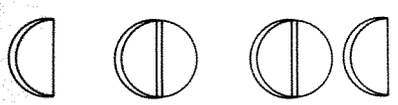
Flexibility promotes optimal response and economy

The wide range of six different tablet strengths—from 10 mg to 150 mg—permits you to prescribe the strength best suited for the individual patient. Because you won't need a new Rx, you can save your patient the cost of an extra prescription fee. And, by prescribing the daily dose at bedtime, you can prescribe the higher strength at the outset and help the patient economize on the prescription price per milligram.

Scored tablets obviate need for new Rx

Half-tablet dosage adjustments with Endep (amitriptyline HCl) are possible because every tablet is scored. You can prescribe a single strength and still have the advantage of adjusting dosage without resorting to a new Rx.

Endep®
amitriptyline HCl/Roche
The half-strength advantage



Before prescribing, please consult complete product information, a summary of which appears on the following page.

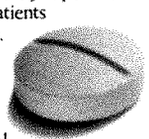
Practicality is a fundamental fact about Endep®

amitriptyline HCl/Roche

Every tablet of Endep (amitriptyline HCl) is scored for precise, convenient adjustment of dosage.

Half-tablet adjustment of dosage does not require a new Rx.

Single daily *h.s.* dosage promotes compliance and economy.

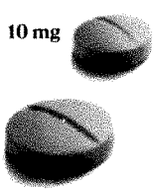


Compliance with practical regimen promotes optimal response.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: To relieve symptoms of depression (notably endogenous depression) and depression accompanied by anxiety.

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.



Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle-closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh possible benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

100 mg

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels.

10 mg

50 mg

25 mg

75 mg

150 mg

Other: Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Dosage: Initiate at low levels, increase gradually, watching for signs of intolerance. As long as 30 days may elapse before adequate antidepressant effect develops; sedative effect may be noted earlier.

Initial Adult Dosage: Outpatients—25 mg *t.i.d.*; may be increased to 150 mg/day. Add increased drug to afternoon and/or bedtime doses. Alternate—50 to 100 mg *h.s.*, gradually increasing *h.s.* dose up to 150 mg/day. Hospitalized Patients—Up to 100 mg/day; increase gradually to 200 mg if necessary. A few patients may require 300 mg/day.

Adolescent and Elderly Patients: In general, 10 mg *t.i.d.* with 20 mg *h.s.* may be satisfactory for those who do not tolerate higher doses.

Maintenance Dosage: With symptomatic improvement, reduce dosage to lowest amount that gives relief, usually 25 mg *b.i.d.* to *q.i.d.*, or 10 mg *q.i.d.* Continue maintenance therapy 3 months or longer to avoid relapse.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. IV administration of 1 to 3 mg physostigmine salicylate reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestations and treatment.

Supplied: 10-mg, 25-mg, 50-mg, 75-mg, 100-mg and 150-mg scored tablets—bottles of 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 60 (10 mg, 25 mg and 50 mg) or 30 (75 mg, 100 mg and 150 mg), available singly and in trays of 10.

The vulnerable ages

The first epileptic seizure is most likely to occur during early childhood and at the onset of puberty

About 9 out of 10 epileptics experience their first seizure before the age of 20—with the highest incidence between 5 and 7, when children start school, and at the onset of puberty, a time of physiological and psychic turmoil.[1] The most common type, grand mal, occurs in approximately 75% of epileptic children,[1] and more than 50% of patients who suffer initially from petit mal develop grand mal seizures before they reach the age of 16.[2]

Mysoline (primidone) for control of grand mal, psychomotor and focal epilepsy

At the onset and afterwards— used alone or as concomitant therapy, MYSOLINE may reduce the frequency and severity of major motor seizures—or even eliminate them. *Excellent* for control of grand mal. Valuable for control of psychomotor[1,3,4] and focal epilepsy as well.[5]

Add Mysoline when control with other anticonvulsants is inadequate—As concomitant therapy, MYSOLINE can improve seizure control in grand mal and psychomotor epilepsy. The combined use of phenobarbital, diphenylhydantoin, and MYSOLINE may have additive anticonvulsant effects without additive side effects.[6]

Change to Mysoline when other anticonvulsants fail— A changeover to MYSOLINE is frequently warranted when other anticonvulsants must be discontinued because of important side effects, or when grand mal seizures are refractory to phenobarbital, with or without diphenylhydantoin.[7]

may be the start of a better life for the epileptic

initial and maintenance therapy for
grand mal, psychomotor and focal epilepsy

BRIEF SUMMARY
(For full prescribing information, see package circular.)

MYSOLINE® Brand of PRIMIDONE
Anticonvulsant

ACTIONS: MYSOLINE acts on the central nervous system to raise seizure threshold or alter seizure pattern. The mechanism(s) of action of anticonvulsant drugs is not known.

Primidone has anticonvulsant activity *per se*. In addition, its two metabolites possess anticonvulsant qualities. The major metabolite is phenylethylmalonamide (PEMA); the other is phenobarbital. In addition to its own anticonvulsant potential, PEMA potentiates phenobarbital.

INDICATIONS: MYSOLINE, either alone or used concomitantly with other anticonvulsants, is indicated in the control of grand mal, psychomotor, and focal epileptic seizures. It may control grand mal seizures refractory to other anticonvulsant therapy.

CONTRAINDICATIONS: Primidone is contraindicated in: 1) patients with porphyria and 2) patients who are hypersensitive to phenobarbital (see ACTIONS).

WARNINGS: The abrupt withdrawal of antiepileptic medication may precipitate status epilepticus.

The therapeutic efficacy of a dosage regimen takes several days before it can be assessed.

Use in pregnancy: Recent reports strongly suggest an association between the use of anticonvulsant drugs by women with epilepsy and an elevated incidence of birth defects in children born to these women. Reference has been made to primidone in several cases in which it was used *in combination* with other anticonvulsants; but its teratogenicity has not been conclusively demonstrated. The possibility exists that other factors, *e.g.*, genetic factors or the epileptic condition, may contribute to the higher incidence of birth defects. The data also indicate that the great majority of mothers receiving anticonvulsant medication deliver normal infants.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and risk to both mother and the unborn child.

When the nature, frequency, and severity of the seizures do not pose a clear threat to the patient, good medical practice requires that the physician weigh the expected therapeutic benefit of anticonvulsant therapy against possible risk on an individual basis.

Neonatal hemorrhage, with a coagulation defect resembling vitamin K deficiency, has been described in newborns whose mothers were taking primidone and other anticonvulsants. Pregnant women under anticonvulsant therapy should receive prophylactic vitamin K_1 therapy for one month prior to, and during, delivery.

The physician should weigh all of the foregoing considerations when treating and counseling epileptic women of childbearing potential.

PRECAUTIONS: The total daily dosage should not exceed 2 Gm. Since MYSOLINE therapy generally extends over prolonged periods, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

In nursing mothers: There is evidence that in mothers treated with primidone, the drug appears in the milk in substantial quantities. Since tests for the presence of primidone in biological fluids are too complex to be carried out in the average clinical laboratory, it is suggested that the presence of undue somnolence and drowsiness in nursing newborns of MYSOLINE-treated mothers be taken as an indication that nursing should be discontinued.

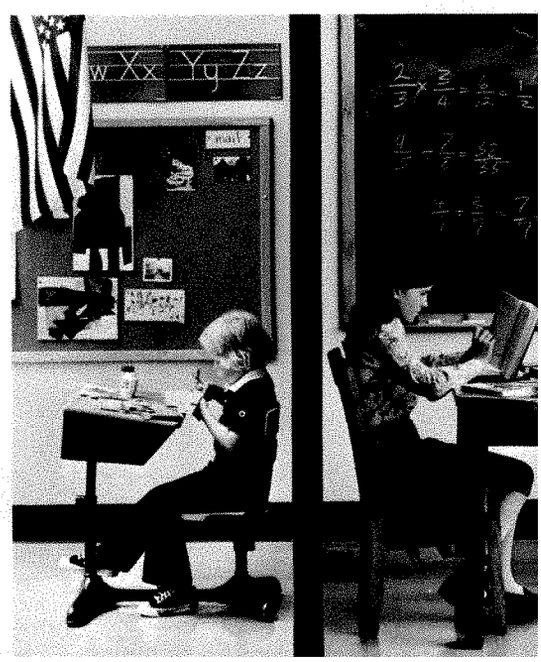
ADVERSE REACTIONS: The most frequently occurring early side effects are ataxia and vertigo. These tend to disappear with continued therapy, or with reduction of initial dosage. Occasionally, the following have been reported: nausea, anorexia, vomiting, fatigue, hyperirritability, emotional disturbances, sexual impotency, diplopia, nystagmus, drowsiness, and morbilliform skin eruptions. Occasionally, persistent or severe side effects may necessitate withdrawal of the drug. Megaloblastic anemia may occur as a rare idiosyncrasy to MYSOLINE and to other anticonvulsants. The anemia responds to folic acid, 15 mg. daily, without necessity of discontinuing medication.

DOSAGE AND ADMINISTRATION: The average adult dose is 0.75 to 1.5 Gm. per day. The initial dose is 250 mg. Increments of 250 mg. are added, usually at weekly intervals, to tolerance, or therapeutic effectiveness, up to daily doses not exceeding 2.0 Gm. A typical dosage schedule for the introduction of MYSOLINE (primidone) is as follows:

Adults and Children Over 8 Years of Age

1st Week 250 mg. daily at bedtime	*2nd Week* 250 mg. b.i.d.
3rd Week 250 mg. t.i.d.	*4th Week* 250 mg. q.i.d.

In children under 8 years of age, maintenance levels are established by a similar schedule, but at one-half the adult dosage. It is best to begin with 125 mg., with gradual weekly increases of 125 mg. a day, to a daily total usually between 500 mg. and 750 mg.



In patients already receiving other anticonvulsants: MYSOLINE should be gradually increased as dosage of the other drug(s) is maintained or gradually decreased. This regimen should be continued until satisfactory dosage level is achieved for combination, or the other medication is completely withdrawn. When therapy with this product alone is the objective, the transition should not be completed in less than two weeks.

MYSOLINE 50 mg. Tablet can be used to practical advantage when small fractional adjustments (upward or downward) may be required, as in the following circumstances:

- for initiation of combination therapy
- during "transfer" therapy
- for added protection in periods of stress or stressful situations that are likely to precipitate seizures (menstruation, allergic episodes, holidays, etc.)

HOW SUPPLIED: MYSOLINE *Tablets*—No. 430—Each tablet contains 250 mg. of primidone (scored), in bottles of 100 and 1,000. Also in unit dose package of 100. No. 431—Each tablet contains 50 mg. of primidone (scored), in bottles of 100 and 500. MYSOLINE *Suspension*—No. 3850—Each 5 cc. (teaspoonful) contains 250 mg. of primidone, in bottles of 8 fluid-ounces.

A Timely New Book from The Joint Information Service

This latest Joint Information Service field study provides a concise, comprehensive overview of the complex matter of the very young American child and his mental health, and then describes in intimate detail seven unique programs for pre-school children with problems—from North Hollywood's Dubnoff Center, emphasizing education as its primary therapeutic modality, to Baltimore's Martin Luther King, Jr. Parent-Child Center, serving two housing projects, served by Johns Hopkins, and largely governed by its own people. All different in treatment approach and philosophy, the programs described are uniform in their dedication to innovation in improving service to the emotionally disturbed very young child, and, equally, to the emotional well being of all young children.

This thoughtful and perceptive description of what has been created by some of the best informed, most experienced and thoughtful specialists in mental health services for very young children should be welcome to all involved in the mental health of children and a casebook for those dealing with child and family mental health.

An articulate exposition of the immense problems and encouraging accomplishments in a particularly difficult area of endeavor . . . . Beyond their concern with the manifestly ill child, the authors intriguingly explore what may be needed to enhance the mental good health of all young children . . . . A significant contribution.

James N. Sussex, M.D.
President, American Association of Psychiatric Services for Children

Tranxene® (IV)

CAPSULES
SINGLE DOSE TABLETS

CLORAZEPATE DIPOTASSIUM 4306CB **Brief Summary**

ACTIONS—Pharmacologically, TRANXENE (clorazepate dipotassium) has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine.

INDICATIONS—TRANXENE is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of TRANXENE for long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS—TRANXENE is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS—TRANXENE is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on TRANXENE should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since TRANXENE has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, TRANXENE is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:

Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:

TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS—In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on TRANXENE for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS—The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION—

For symptomatic relief of anxiety:

TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose daily at bedtime; the recommended initial dose is 15 mg. After the initial dose, the response of the patient may require adjustment of subsequent dosage. Lower doses may be indicated in the elderly patient. Drowsiness may occur at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single dose every 24 hours. This tablet is intended as an alternate dosage form for the convenience of patients stabilized on a dose of 7.5 mg. capsules three times a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be administered as a single dose every 24 hours.

For symptomatic relief of acute alcohol withdrawal:

Recommended schedule: 1st 24 hours, 30 mg TRANXENE initially, followed by 30 to 60 mg in divided doses; 2nd 24 hours, 45 to 90 mg in divided doses; 3rd 24 hours, 22.5 to 45 mg in divided doses; 4th day, 15 to 30 mg in divided doses. Thereafter gradually reduce to 7.5 to 15 mg daily, and discontinue as soon as condition is stable. Maximum daily dose is 90 mg. Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS—If TRANXENE is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. Animal experience indicates that TRANXENE prolongs the sleeping time after hexobarbital or after ethyl alcohol, increases the inhibitory effects of chlorpromazine, but does not exhibit monoamine oxidase inhibition. Clinical studies have shown increased sedation with concurrent hypnotic medications. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If TRANXENE (clorazepate dipotassium) is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

MANAGEMENT OF OVERDOSAGE—Overdosage is usually manifested by varying degrees of CNS depression ranging from slight sedation to coma. As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatment of overdosage should consist of the general measures employed in the management of overdosage of any CNS depressant. Gastric evacuation either by the induction of emesis, lavage, or both, should be performed immediately. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though rarely reported, may occur with large overdoses. In such cases the use of agents such as Levophed® (levarterenol) or Aramine® (metaraminol) should be considered.

While reports indicate that individuals have survived overdoses of TRANXENE as high as 450 to 675 mg., these doses are not necessarily an accurate indication of the amount of drug absorbed, since the time interval between ingestion and the institution of treatment was not always known. Sedation in varying degrees was the most common physiological manifestation of TRANXENE overdosage. Deep coma when it occurred was usually associated with the ingestion of other drugs in addition to TRANXENE.

CLINICAL PHARMACOLOGY—Studies in healthy men have shown that TRANXENE has depressant effects on the central nervous system. Prolonged administration of single daily doses as high as 120 mg. was without toxic effects. Abrupt cessation of high doses was followed in some patients by nervousness, insomnia, irritability, diarrhea, muscle aches, or memory impairment.

Absorption–Excretion:

After oral administration of TRANXENE, there is essentially no circulating parent drug. Nordiazepam, its primary metabolite, quickly appears in the blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-TRANXENE, about 80% was recovered in the urine and feces within 10 days. Excretion was primarily in the urine with about 1% excreted per day on day 10.

HOW SUPPLIED—TRANXENE (clorazepate dipotassium) is supplied as capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 (NDC 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).

7.5 mg. capsules (gray with maroon cap) in bottles of 100 (NDC 0074-3418-13) and 500 (NDC 0074-3418-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3418-11).

15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) and 500 (NDC 0074-3419-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage strengths:

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in bottles of 100 (NDC 0074-2699-13).

7043191/R

A prudent prescription for today's anxious patient

A different tranquilizer. Times change. Today's patient has changed. And the physician's most prudent choice of therapy for anxious patients may also change. Thus if you are now thinking about changing your choice of minor tranquilizers, consider Tranxene.

A change of look. Tranxene is a physically distinctive change of therapy. It's very different in form and appearance from any other tranquilizers your patients have previously received or seen.

Greater versatility. Its added dosage options are different too. They permit not only conventional divided doses, but also convenient once-a-day regimens . . . including an ultrasimple single dose tablet (11.25 mg) especially suited to elderly patients.

Yet the same effectiveness. Prescribe with confidence. In numerous published studies involving hundreds of patients, Tranxene has been shown to be clinically equivalent to diazepam in treating anxiety.

Tranxene® 4306CB C IV
CLORAZEPATE DIPOTASSIUM

Maybe it's time?

LIBRARY

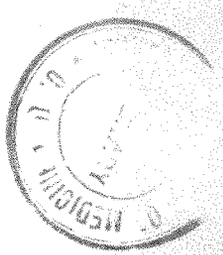
In this issue

Psychotherapies: An Overview
By Toksoz B. Karasu

OFFICIAL JOURNAL OF THE
AMERICAN PSYCHIATRIC ASSOCIATION

One of a series from "The Many Faces of

STELAZINE®
brand of
trifluoperazine HCl
in Psychiatry,"
a transcultural look at masks as symbols



Eskimo Finger Mask, Koskokwin River, Alaska.
Used by shaman as wand to drive out evil spirits.
Also used by women in ceremonial dances.

From the collection of the University Museum,
University of Pennsylvania, Philadelphia, Pa.
Reproduced with permission.

LIFT THE MASK OF SCHIZOPHRENIC SYMPTOMS

'Stelazine' provides effective control of hallucinations, delusions, anxiety and other psychotic symptoms.
With its apparent activating effect, 'Stelazine' is especially useful in withdrawn, apathetic or detached patients.

- Controls psychotic symptoms
- Seldom causes excessive sedation
- Convenient b.i.d. dosage

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications
Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
Effective: For the management of the manifestations of psychotic disorders.
Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.
'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.
Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.
Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.
Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).
Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg., and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only) 10 mg./ml.

SK&F CO.

INSTITUTE ON HOSPITAL & COMMUNITY PSYCHIATRY

St. Francis Hotel
San Francisco, California
October 3–6, 1977

APA PLACEMENT SERVICE
For Employers and Applicants

Those wishing to announce either position openings or availability for employment may register in advance by requesting a listing form by calling Ms. M. J. Merrick (202) 232-7878, ext. 326, or writing to her attention at APA Central Office, 1700 18th Street, N.W., Washington, D.C. 20009. Listing forms should be returned no later than September 26th. On-site listings will also be accepted. However, forms received at the APA prior to the September 26th deadline will have exposure from the very beginning of the Institute. There will be a Placement booth and an interviewing area located in the Institute Registration area (Georgian Room) at the St. Francis Hotel. Listings will be accepted for any mental health related position vacancy/availability.

APPLICANTS—$3 for listing availability
EMPLOYERS—$5 for listing job description

Complete sets of either all applicants or all positions will be available at the close of the Institute at $10 per set.

THE AMERICAN JOURNAL OF PSYCHIATRY

OFFICIAL JOURNAL OF THE
AMERICAN PSYCHIATRIC ASSOCIATION

The American Journal of Psychiatry, formerly *The American Journal of Insanity*, is published monthly by the American Psychiatric Association. Editorial office: 1700 Eighteenth Street, N.W., Washington, D.C. 20009; telephone (202) 797-4918.

Subscriptions: U.S. $18.00 per year, Canada and South America $19.00, other foreign $22.00; single issues: $2.25 plus postage.

Business communications and changes of address from APA members should be directed to the Division of Membership Services and Studies. Communications from non-member subscribers should be directed to the Circulation Department, American Psychiatric Association, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Four to six weeks advance notice is required for changes of address.

Advertising representatives: Steven K. Herlitz, Inc., 850 Third Avenue, New York, N.Y. 10022.

Type set by Byrd PrePress, 5408 Port Royal Road, Springfield, Va. 22151.

Printed by Dartmouth Printing Co., 69 Lyme Road, Hanover, N.H. 03755.

Second class postage paid at Washington, D.C., and additional mailing offices.

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit 3 copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later. Annual meeting papers should not be submitted to the *Journal* until *after* the annual meeting.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

All communications about a manuscript should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; with other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, the copyright of all parts of the paper, including any illustrations, passes from the author to the *Journal*. Written permission to reprint material published in the *Journal* must first be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for this permission.

Informed consent. Manuscripts that report the results of experimental investigation on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure had been fully explained.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

SPECIFICATIONS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond paper. **All parts of the manuscript** (including case reports, footnotes, references, etc.) **should be double spaced,** with margins of 2½-3¾ cm (1-1½ inches) at the top, bottom, and both sides. Subheads should be inserted at reasonable intervals. All abbreviations should be explained. All measurements must be in metric units.

Length. All pages of the manuscript must be numbered, including references, tables, and figures. The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles: 3,800 words or the equivalent including references, tables, and figures (about 15 manuscript pages). Brief Communications: 2,500 words or the equivalent (about 10 manuscript pages); see stipulations above. Clinical and Research Reports: 1,000 words. 10 references, 1 table. Letters to the Editor: 500 words. Please write the total number of words and the number of tables and figures on the title page of the submitted material.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the coauthor who has been designated to assume responsibility for the paper and reprint requests. Authors named in the by-line should be limited to principal researchers and writers; other collaborators may be acknowledged in a footnote.

Precis. A brief precis (60–100 words for regular articles, 40–60 words for Brief Communications) is included at the beginning of each article. The author may prepare the precis or ask that the *Journal* staff prepare it.

References. References should be typed **double spaced** on a separate sheet of paper. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Tables and figures should be self-explanatory and should supplement, not duplicate, text. See recent issues of the *Journal* for general style.

Each table should be typed double spaced on a separate sheet attached at the end of the manuscript. Columns of like material should read down, not across.

One complete set of figures, in the form of glossy prints, should be submitted. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Graphs should be finished drawings not requiring further artwork. Authors are urged to engage professional assistance in the preparation of figures and may be charged for any further artwork that must be done in the editorial office.

AUTHORS CORRECTIONS

After the paper has been scheduled for publication, the edited manuscript will be sent to the first-named author for corrections and answers to queries. Prompt return is necessary. If an author expects to be away from his office for a long period of time after being notified of the acceptance of his paper, he should inform the *Journal* office or arrange with a coauthor to assume responsibility for the paper. Galley proofs will not be sent to authors.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Requests from others to order reprints should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

Hallucinations and delusions rapidly controlled

Trapped by unrealistic perceptions...

...and terrified by his hallucinations and delusions on admission. Because Navane (thiothixene) is particularly effective in controlling these symptoms and their resulting suspiciousness and anxiety, it can provide the essential first step toward restoring stabilization and facilitating the development of purposeful activity. Extensive clinical data and widespread experience confirm the effectiveness of Navane in rapidly controlling such typical psychotic behavior on admission.

Long-term therapy is facilitated...

...because Navane offers an unsurpassed safety record among effective neuroleptic agents, permitting continuing control of symptoms of psychoses such as hallucinations and delusions. Like other antipsychotic agents, extrapyramidal symptoms may occur, but are readily controlled through dosage adjustments or antiparkinsonian agents. Cardiovascular effects such as hypotension, and hepatic or hematopoietic effects rarely occur and are generally mild and transient, with no jaundice or agranulocytosis reported to date.

An effective first step towards discharge...

Navane®

(thiothixene) (thiothixene HCl)

Capsules 1 mg., 2 mg., 5 mg., 10 mg., 20 mg. Concentrate 5 mg./ml.—Intramuscular 2 mg./ml.

For prescribing information, including adverse reactions and contraindications, please see following page of this advertisement.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals
New York, New York 10017

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Actions. Navane is a psychotropic agent of the thioxanthene series. Navane possesses certain chemical and pharmacological similarities to the piperazine phenothiazines and differences from the aliphatic group of phenothiazines. Navane's mode of action has not been clearly established.

Indications. Navane is effective in the management of manifestations of psychotic disorders.

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy* – Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children–The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration – As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane. Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudoparkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leucocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution–For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate–In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor elevating action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg. of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

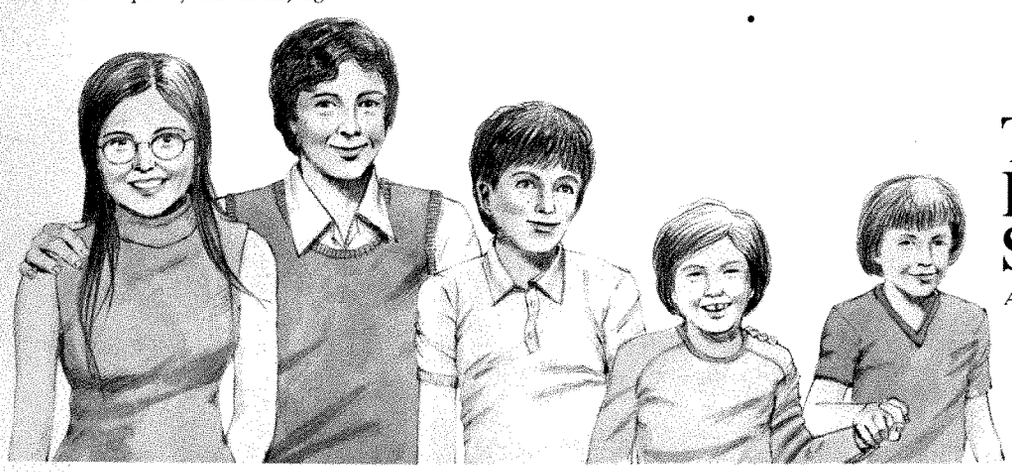
Flexibility is our forte: The Brown Schools

Because we maintain great flexibility at all three of our treatment centers, each resident follows an individualized plan of treatment, training, education and care prescribed for that resident alone.

And we believe that residential treatment conducted in this highly individualized manner still is the most effective treatment for many. Our large, experienced staff is skilled in the treatment of children, adolescents and adults with learning disabilities, neurological impairment, mental retardation or emotional disturbance.



Our three treatment centers are geographically separated to provide the appropriate residential milieu, yet close enough that residents benefit from the comprehensive training and expertise of the entire staff. All three are psychiatrically oriented, so that we are prepared to treat emotional disturbance in persons of any intellectual capacity and of any age.

Basic tool of modern psychiatry

Thorazine®

Tablets: 25 and 50 mg of the HCl

brand of **chlorpromazine**

- Effective control of psychotic symptoms
- Especially useful in agitated, violent or anxious schizophrenic patients
- Unsurpassed clinical experience
- 18 convenient dosage forms and strengths

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences – National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings:

Caution is recommended when 'Thorazine' is administered for the treatment of vomiting in children.

Antiemetics are not recommended to treat uncomplicated short-term vomiting in children or vomiting of unknown etiology.

The possibility of extrapyramidal reactions from 'Thorazine' may confuse the diagnosis of Reye's syndrome or other encephalopathy. Although unconfirmed, some suspicion exists that centrally-acting antiemetics may contribute to or adversely affect the course of Reye's syndrome, and should be avoided in suspected cases.

©1967, 1968, 1969 SmithKline Corporation

Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

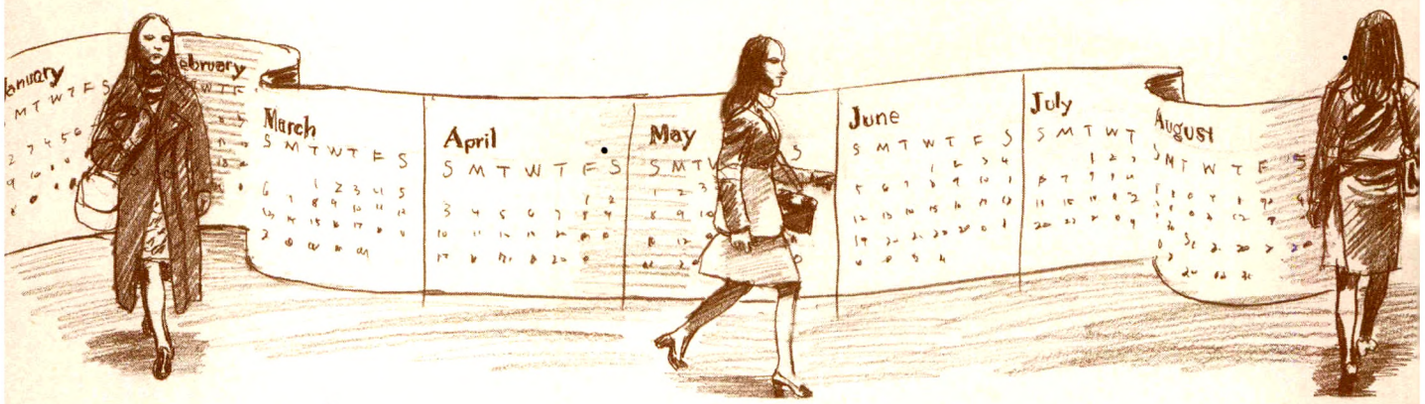
Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudoparkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.

NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.



Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; Single Unit Packages of 100 (intended for institutional use only). Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only). Injection, 25 mg./ml.: Syrup, 10 mg./5 ml.: Suppositories, 25 mg. and 100 mg. Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

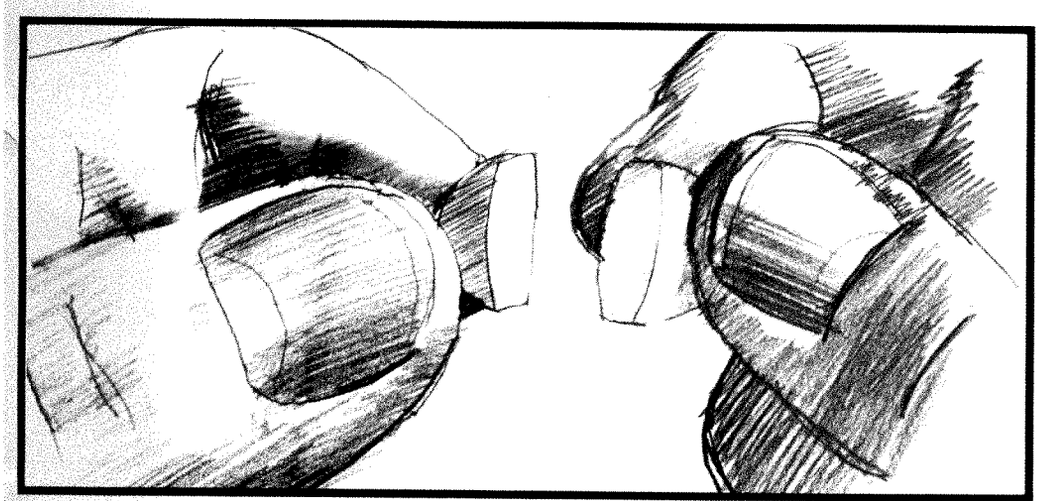
Helps Return Patients to Reality

Why Endep® makes
with amitriptyline HC

Scored tablets h.s. enhance compliance and tolerability

Once you select the appropriate maintenance dose, you can prescribe a single tablet of Endep h.s. secure in the knowledge that you can adjust the dose by a half tablet without requiring the patient to obtain a new Rx. The simplicity of this h.s. schedule not only encourages compliance, but lessens the likelihood of anticholinergic and sedative side effects during daytime.

Scored tablets h.s. reduce confusion



Bedtime dosage means that the patient has only one dose of Endep to remember, thus minimizing possible confusion with other medications taken concomitantly. The built-in flexibility of the scored tablet permits half-strength dosage adjustments without confusing the patient with a new color or size of medication.

ROCHE

long-term maintenance more practical:

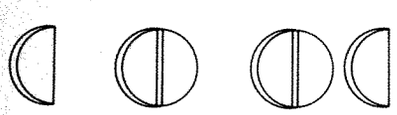
Scored tablets h.s. promote economy

The economy of Endep (amitriptyline HCl) is particularly evident during long-term maintenance therapy, when your patient is purchasing refills of the single strength you have prescribed. The h.s. schedule enables you to prescribe a single strength in place of a more expensive multiple-dose prescription. The scored tablet permits you to adjust the regimen without putting the patient through the expense of a new prescription fee, without wasting tablets and without necessitating the purchase of more costly multiple-dose refills.

Endep®

amitriptyline HCl / Roche

The half-strength advantage



Before prescribing, please see following page for a summary of product information.

Practicality is a fundamental fact about Endep®

amitriptyline HCl/Roche

Every tablet of Endep (amitriptyline HCl) is scored for precise, convenient adjustment of dosage.

Half-tablet adjustment of dosage does not require a new Rx.

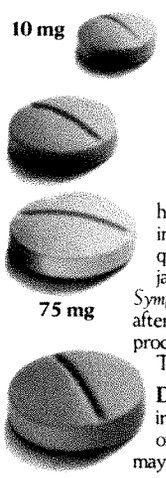
Single daily *h.s.* dosage promotes compliance and economy.

Compliance with practical regimen promotes optimal response.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: To relieve symptoms of depression (notably endogenous depression) and depression accompanied by anxiety.

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.



Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle-closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh possible benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

100 mg

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels.

10 mg

50 mg

25 mg

75 mg

150 mg

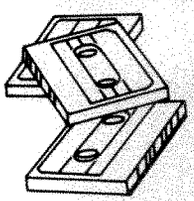
Other: Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Dosage: Initiate at low levels, increase gradually, watching for signs of intolerance. As long as 30 days may elapse before adequate antidepressant effect develops; sedative effect may be noted earlier.

Initial Adult Dosage: Outpatients—25 mg *t.i.d.*; may be increased to 150 mg/day. Add increased drug to afternoon and/or bedtime doses. Alternate—50 to 100 mg *h.s.*, gradually increasing *h.s.* dose up to 150 mg/day. Hospitalized Patients—Up to 100 mg/day; increase gradually to 200 mg if necessary. A few patients may require 300 mg/day.

Adolescent and Elderly Patients: In general, 10 mg *t.i.d.* with 20 mg *h.s.* may be satisfactory for those who do not tolerate higher doses.

Maintenance Dosage: With symptomatic improvement, reduce dosage to lowest amount that gives relief, usually 25 mg *b.i.d.* to *q.i.d.*, or 10 mg *q.i.d.* Continue maintenance therapy 3 months or longer to avoid relapse.



Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. IV administration of 1 to 3 mg physostigmine salicylate reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestations and treatment.

Supplied: 10-mg, 25-mg, 50-mg, 75-mg, 100-mg and 150-mg scored tablets—bottles of 100 and 500, Tel-E-Dose® packages of 100; Prescription Paks of 60 (10 mg, 25 mg and 50 mg) or 30 (75 mg, 100 mg and 150 mg), available singly and in trays of 10.

Amphetamines work in MBD.
Methylphenidate works in MBD.

Then why Cylert® for MBD?

(pemoline)

Because Cylert offers a lot:

- Once-a-day dosage at home
- Elimination of mid-day school dose and need for school personnel supervision
- Avoids ups and downs of drug action brought about by multiple daily dosage
- Control of medication by the parent
- A chewable dosage form
- Less physician paper work (Cylert is in schedule IV)
- Safety and efficacy proven in extensive clinical studies*

*Copy of the Cylert Monograph available on written request.

Dosage and administration

Cylert is administered as a single oral dose each morning.

The recommended starting dose is 37.5 mg/day. This daily dose should be gradually increased by 18.75 mg at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with Cylert is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration. Drug administration should be interrupted occasionally (once or twice a year) to determine if behavioral symptoms are sufficient to require continued therapy.

When not to use medication

Cylert should not be used for (and will not be effective in) simple cases of overactivity in school age children.

Neither should it be used in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

The physician should rely on a complete history of the child and a thorough description of symptoms from both parents and teacher before postulating a diagnosis of MBD.

ABBOTT

Please see next page for Prescribing Information.

708 3202

Cylert and Cylert Chewable Tablets

(pemoline)

Prescribing Information

Description: Cylert (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

Cylert (pemoline) is supplied as tablets for oral administration.

Clinical Pharmacology: Cylert (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. Cylert is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

Cylert (pemoline) has a gradual onset of action in children with minimal brain dysfunction. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

Indications: *MINIMAL BRAIN DYSFUNCTION IN CHILDREN*—as adjunctive therapy to other remedial measures (psychological, educational, social).

Special Diagnostic Considerations: The cause of minimal brain dysfunction (MBD) is unknown. Diagnosis of MBD involves the use of medical, psychological, educational, and social tools, since no single diagnostic test is adequate.

MBD is characterized by chronic moderate to severe hyperactivity, short attention span, distractibility, emotional lability, and impulsivity. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. In the primary therapy of MBD, appropriate educational placement is essential and psychosocial intervention is generally necessary. When these measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

Contraindications: Cylert (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

Warnings: Cylert is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Sufficient data on the safety and the efficacy of the long-term use of Cylert in children with minimal brain dysfunction are not yet available.

A temporary suppression of the predicted growth rate (weight and/or height gain) has been reported for children receiving long-term stimulant therapy. A definite causal relationship between stimulant drugs and this finding has not been established.

Precautions: Liver function tests should be performed periodically during therapy with Cylert. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

Cylert should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of Cylert with other drugs has not been studied in humans. Patients who are receiving Cylert concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

Cylert failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with Cylert. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. Cylert should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of Cylert (pemoline) for use during pregnancy and lactation has not been established.

Fertility, reproduction, and teratology studies were conducted in laboratory animals. Pemoline, in doses of 18.75 or 37.5 mg./kg./day, had no effect on the fertility of male or female rats. The drug, when given to pregnant rats (from gestation day 15 through weaning) and to rabbits (from gestation days 6-18) at these same dosage levels, produced no teratogenic or embryotoxic effects, and had no effect on the viability of the young at birth. However, increased incidences of stillbirths and cannabilization were observed when pemoline was given to rats at these dosage levels, beginning 14 days prior to conception.

Adverse Reactions: Insomnia is the most frequently reported side effect of Cylert; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking Cylert, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking Cylert; a causal relationship between the drug and this clinical finding has not been established.

There have been reports of dyskinetic movements of the lips, face, and extremities occurring with the use of Cylert. Convulsive seizures have also been reported. A definite causal relationship between Cylert and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with Cylert often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

Overdosage: Signs and symptoms of acute Cylert overdosage may include agitation, restlessness, hallucinations, tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of preliminary studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of Cylert overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

Dosage and Administration: Cylert (pemoline) is administered as a single oral dose each morning.

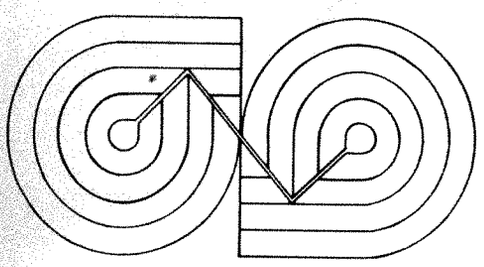
The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with Cylert is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration. Drug administration should be interrupted occasionally (once or twice a year) to determine if behavioral symptoms are sufficient to require continued therapy.

How Supplied: Cylert (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

18.75 mg. tablets (yellow-colored) in bottles of 100 (NDC 0074-6025-13)

37.5 mg. tablets (orange-colored) in bottles of 100 (NDC 0074-6057-13)



75 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-6073-13)

Cylert Chewable is supplied as monogrammed, grooved tablets in one dosage strength:

37.5 mg. tablets (orange-colored) in bottles of 100 (NDC 0074-6088-13)

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

PKSAP-III REGISTRATION FORM — CONTINUOUS OFFERING

Please make check payable to APA, PKSAP-III. Mail to: Publication Sales, APA, 1700 18th Street, N.W., Washington, D.C. 20009

From the Sleep Research Laboratory:

Dalmane® (flurazepam HCl) proved the most effective hypnotic over 14 nights...[1]

For those patients who need it, Dalmane (flurazepam HCl) alone provides continued effectiveness[2,3]

Since insomnia is often transient and intermittent, the prolonged administration of a hypnotic is generally not necessary or recommended. But for those patients whose insomnia is a chronic problem, the continued effectiveness of Dalmane is a decided benefit. Even at the end of a 28-night medication period, patients with chronic insomnia were falling asleep faster, spending less time awake during the night, and sleeping substantially longer on Dalmane 30 mg *h.s.* than on baseline placebo nights (average results). This effectiveness was proved[2] and confirmed[3] in two independent sleep research studies using a new 47-night protocol. When similarly evaluated, pentobarbital was ineffective at the end of two weeks.[2]

TOTAL SLEEP TIME (MEAN)[3]
(5 patients with insomnia)

*Significantly increased over baseline placebo ($p < .05$)

14 consecutive nights:
3 in sleep laboratory, 8 at home,
3 in sleep laboratory

...and now, the only one proved effective over 28 nights.[2,3]

In previous studies,[1] chloral hydrate and glutethimide lost most or all effectiveness

In fact, continued effectiveness for both inducing and maintaining sleep over 14 consecutive nights[1] has long been an exclusive benefit of Dalmane. No other available sleep agent, including chloral hydrate or glutethimide,[1] has been able to demonstrate such effectiveness in the sleep research laboratory.

The safety record of Dalmane (flurazepam HCl) is well established

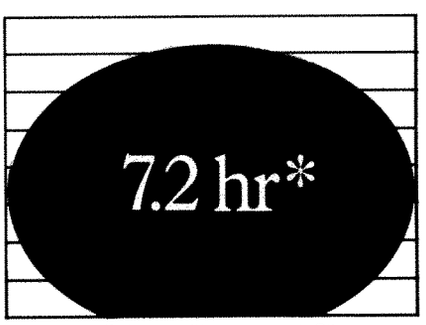
Dalmane is relatively safe and well tolerated. Prolonged administration is not generally necessary, but if used repeatedly, periodic blood counts and liver and kidney function tests should be performed.

Dalmane®
(flurazepam HCl)

relatively safe...
no need
to increase
dosage

ROCHE

28 consecutive nights:
3 in sleep laboratory, 7 at home,
4 in sleep laboratory, 10 at home,
4 in sleep laboratory[3]



Please see following page for a summary of product information.

1,5,7,14,28 nights... as needed, the effectiveness of Dalmane® one *h.s.* (flurazepam HCl) C-IV meets the challenge of insomnia

One 30-mg capsule *h.s.*—usual adult dosage (15 mg may suffice in some patients).
One 15-mg capsule *h.s.*—initial dosage for elderly or debilitated patients.

- **Patients fall asleep rapidly, sleep longer on a single *h.s.* dose**
- **Nighttime awakenings and time spent awake are reduced**
- **Effectiveness maintained without dosage increase from night to night**
- **Patients generally awaken refreshed; morning "hangover" is infrequent**

TOTAL SLEEP TIME (OVERALL MEAN)[3]
(5 patients with insomnia)

Dalmane (flurazepam HCl)
nights 1-3, 12-14, 26-28

*Significantly increased over baseline placebo ($p < .05$).

1. Kales A, *et al*: *Arch Gen Psychiatry* *23*:226-232, Sep 1970
2. Kales A, *et al*: *Clin Pharmacol Ther* *18*:356-363, Sep 1975
3. Dement WC, *et al*: Long-term effectiveness of flurazepam 30 mg *h.s.* on chronic insomniacs. Presented at the 15th annual meeting of the Association for Psychophysiological Study of Sleep, Edinburgh, Scotland, Jun 30-Jul 4, 1975

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).

***Usage in Pregnancy:* Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane (flurazepam HCl), a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated, limit initial dosage to 15 mg to preclude oversedation, dizziness and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies. Periodic blood counts and liver and kidney function tests are advised during repeated therapy. Observe usual precautions in presence of impaired renal or hepatic function.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect. *Adults:* 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

The American Psychiatric Association announces publication of two volumes reporting the Conference on Education of Psychiatrists

held at Lake of the Ozarks, Missouri, June 9-15, 1975. Organized by the A.P.A. in cooperation with the American Academy of Child Psychiatry, the American Association of Chairmen of Departments of Psychiatry, and the American Association of Directors of Psychiatric Residency Training.

1. PSYCHIATRIC EDUCATION: PROLOGUE TO THE 1980's, Library Bound, 544 pages, $15.00.

This is a substantive, highly readable, report of the Conference, written by Anne H. Rosenfeld with an Editorial Board comprising: Ewald W. Busse, M.D., Chairperson of the Conference, Walter E. Barton, M.D., Bernard Holland, M.D., Donna Norris, M.D., Melvin Sabshin, M.D., Jeanne Spurlock, M.D., and Robert L. Robinson, M.A. (Staff Consultant).

The volume contains ten chapters covering the topical structure of the Conference: Goals and Values; Competence, Evaluation, and Quality Control; The Resident; Faculty; Educational Methods: Means in the Service of Ends; The Program Environment; Research; The Economics of Residency Training; Psychiatry in Its Social Context; and Retrospect and Prospect. It also contains nine appendices describing the organization of the Conference and its participants, together with selected model programs and related informational materials of value.

2. THE WORKING PAPERS OF THE 1975 CONFERENCE ON EDUCATION OF PSYCHIATRISTS Paper bound, 432 pages, $12.50.

Sixty two leading psychiatric educators served on seven preparatory commissions, one for each of seven topic areas, and prepared advance working papers as a basis for Conference deliberations. The topics and Commission Chairpersons were: Social Issues and Needs (James N. Sussex, M.D.); Goals and Objectives (Morton F. Reiser, M.D.); The Resident (David R. Hawkins, M.D.); Content, Methodology, Faculty and Environment (Milton Greenblatt, M.D.); Research (Daniel X. Freedman, M.D.); Economics (Herzl Spiro, M.D.); Evaluation and Quality Control (Eric Pfeiffer, M.D.). The Chairpersons, together with the Conference Chairperson, served as the Editorial Board for this volume.

Papers commenting on the reports of the commissions, published here for the first time, were presented at the Conference by Melvin Sabshin, M.D., Eugene B. Brody, M.D., Jeanne Spurlock, M.D., Jack R. Ewalt, M.D., Robert J. Stoller, M.D., James R. Comer, M.D., and Bernard Holland, M.D.

in clinically significant depression...

penetrating the symptom barrier to productive psychotherapy

symptoms often interfere with therapy

In clinically significant depression, the patient often becomes barricaded behind his own symptoms during psychotherapy. Because these symptoms can be so sharply defined and somatic in expression, he may reject the fact that they are psychic in origin. Sleep disturbance, gastrointestinal complaints, anorexia, chronic fatigue, and other psychosomatic symptoms may so preoccupy—or overwhelm—the depressed patient that truly productive therapeutic sessions are difficult to achieve. Instead of being able to concentrate on the core emotional problems of the depression itself, he may for example go on at length about how broken his sleep is or keep reiterating (while the therapeutic hour slips by) how physically miserable he feels.

ELAVIL®
(AMITRIPTYLINE HCl, MSD)
to help penetrate the symptom barrier in depression requiring medication

ELAVIL, a highly effective tricyclic antidepressant, will often alleviate these symptoms. With the help of ELAVIL, sleep disturbance—so common in clinically depressed patients and often the symptom that distresses them most—as

well as other "barrier symptoms" may be lessened to the point where they no longer come between you and the patient.

psychotherapy takes direction

As these preoccupying complaints are lifted, psychotherapy sessions can become more productive. Patients are enabled to respond more fruitfully during therapeutic hours and to resume or pursue more efficiently the necessary activities in their personal lives.

meeting therapeutic goals

And as the antidepressant activity of ELAVIL (Amitriptyline HCl, MSD) takes hold, it helps relieve the depressive condition itself. Sometimes only a minimum of actual psychotherapy is required. The patient may experience a more rapid recovery—while you conserve valuable time.

Prescribe ELAVIL then, to help lighten the patient's burden in depression—and yours in its management.

ELAVIL should not be used during the acute recovery phase following myocardial infarction; in patients hypersensitive to it; in those who have received an MAOI within two weeks; or in children under 12. Patients with cardiovascular disorders should be watched closely. Safe use during pregnancy and lactation has not been established. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Hospitalize as soon as possible any patient suspected of having taken an overdose.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
INJECTION: 10 mg per ml

ELAVIL®
(AMITRIPTYLINE HCl | MSD)

an antidepressant with an anxiety-reducing sedative component to its action

MSD
MERCK SHARP & DOHME

addendum

To further simplify once-daily therapy for many depressed patients

Tablets

ELAVIL®

(AMITRIPTYLINE HCl | MSD)

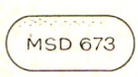
ONE TABLET, ONCE DAILY

—an appropriate way to prescribe for many depressed adult outpatients. Because of its simplicity, this regimen helps improve patient compliance. Of course, ELAVIL may also be prescribed in divided daily doses.

ONCE-DAILY DOSAGE SCHEDULE FOR ADULT OUTPATIENTS:

A single 75-mg tablet
Usual starting dosage

A single 100-mg tablet
Maximum starting dosage



A single 50-mg tablet
Minimum starting dosage

Dosage may be increased by 25 or 50 mg as necessary until a total of 150 mg per day is reached.

A single 150-mg tablet
Maximum daily dosage

ELAVIL MAY ALSO BE PRESCRIBED IN DIVIDED DAILY DOSES

The 25-mg tablet

This strength may prove useful when therapy is initiated with divided daily doses in adult outpatients. Starting dosage is usually 75 mg daily. If necessary, this dosage may be increased gradually to a total of 150 mg a day. Increases are made preferably in the late afternoon or bedtime dose.

The 10-mg tablet

This strength may prove useful for patients who require lower doses, e.g., adolescent and elderly patients. For these patients who can not tolerate higher doses, 10 mg three times a day with 20 mg at bedtime may be satisfactory.

A sedative effect may be apparent before the antidepressant effect of ELAVIL is noted. An adequate therapeutic effect may take as long as 30 days to develop.

NOTE: The usual maintenance dosage of ELAVIL is 50 to 100 mg per day which may be given in a single dose preferably at bedtime. In some patients 40 mg per day is sufficient. This drug is not recommended for patients under 12 years of age.

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.
When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

ELAVIL®
(AMITRIPTYLINE HCl, MSD)

MSD
MERCK SHARP & DOHME

In the psychoneurotic patient, the pattern of anxiety – psychophysiological complaints and secondary depressive symptoms – often responds to Valium®(diazepam)

ROCHE

Before prescribing, please consult complete product information, a summary of which appears on the following page.

In the psychoneurotic patient

Valium® (diazepam) IV

2-mg, 5-mg, 10-mg scored tablets

can relieve anxiety and its secondary depressive symptoms

Initial calming in hours

Your anxious psychoneurotic patient will find the prompt antianxiety action of Valium (diazepam) highly reassuring. It's immediate, tangible proof that his medication is working.

Significant improvement in days

As Valium reduces overwhelming symptoms of anxiety and psychic tension, your patient begins to feel better often within a few days.

Patient response you know, want and trust

You've come to expect a certain kind of response with Valium—and that's the kind you usually get. A pronounced antianxiety response. A response that starts to benefit the anxious patient almost immediately.

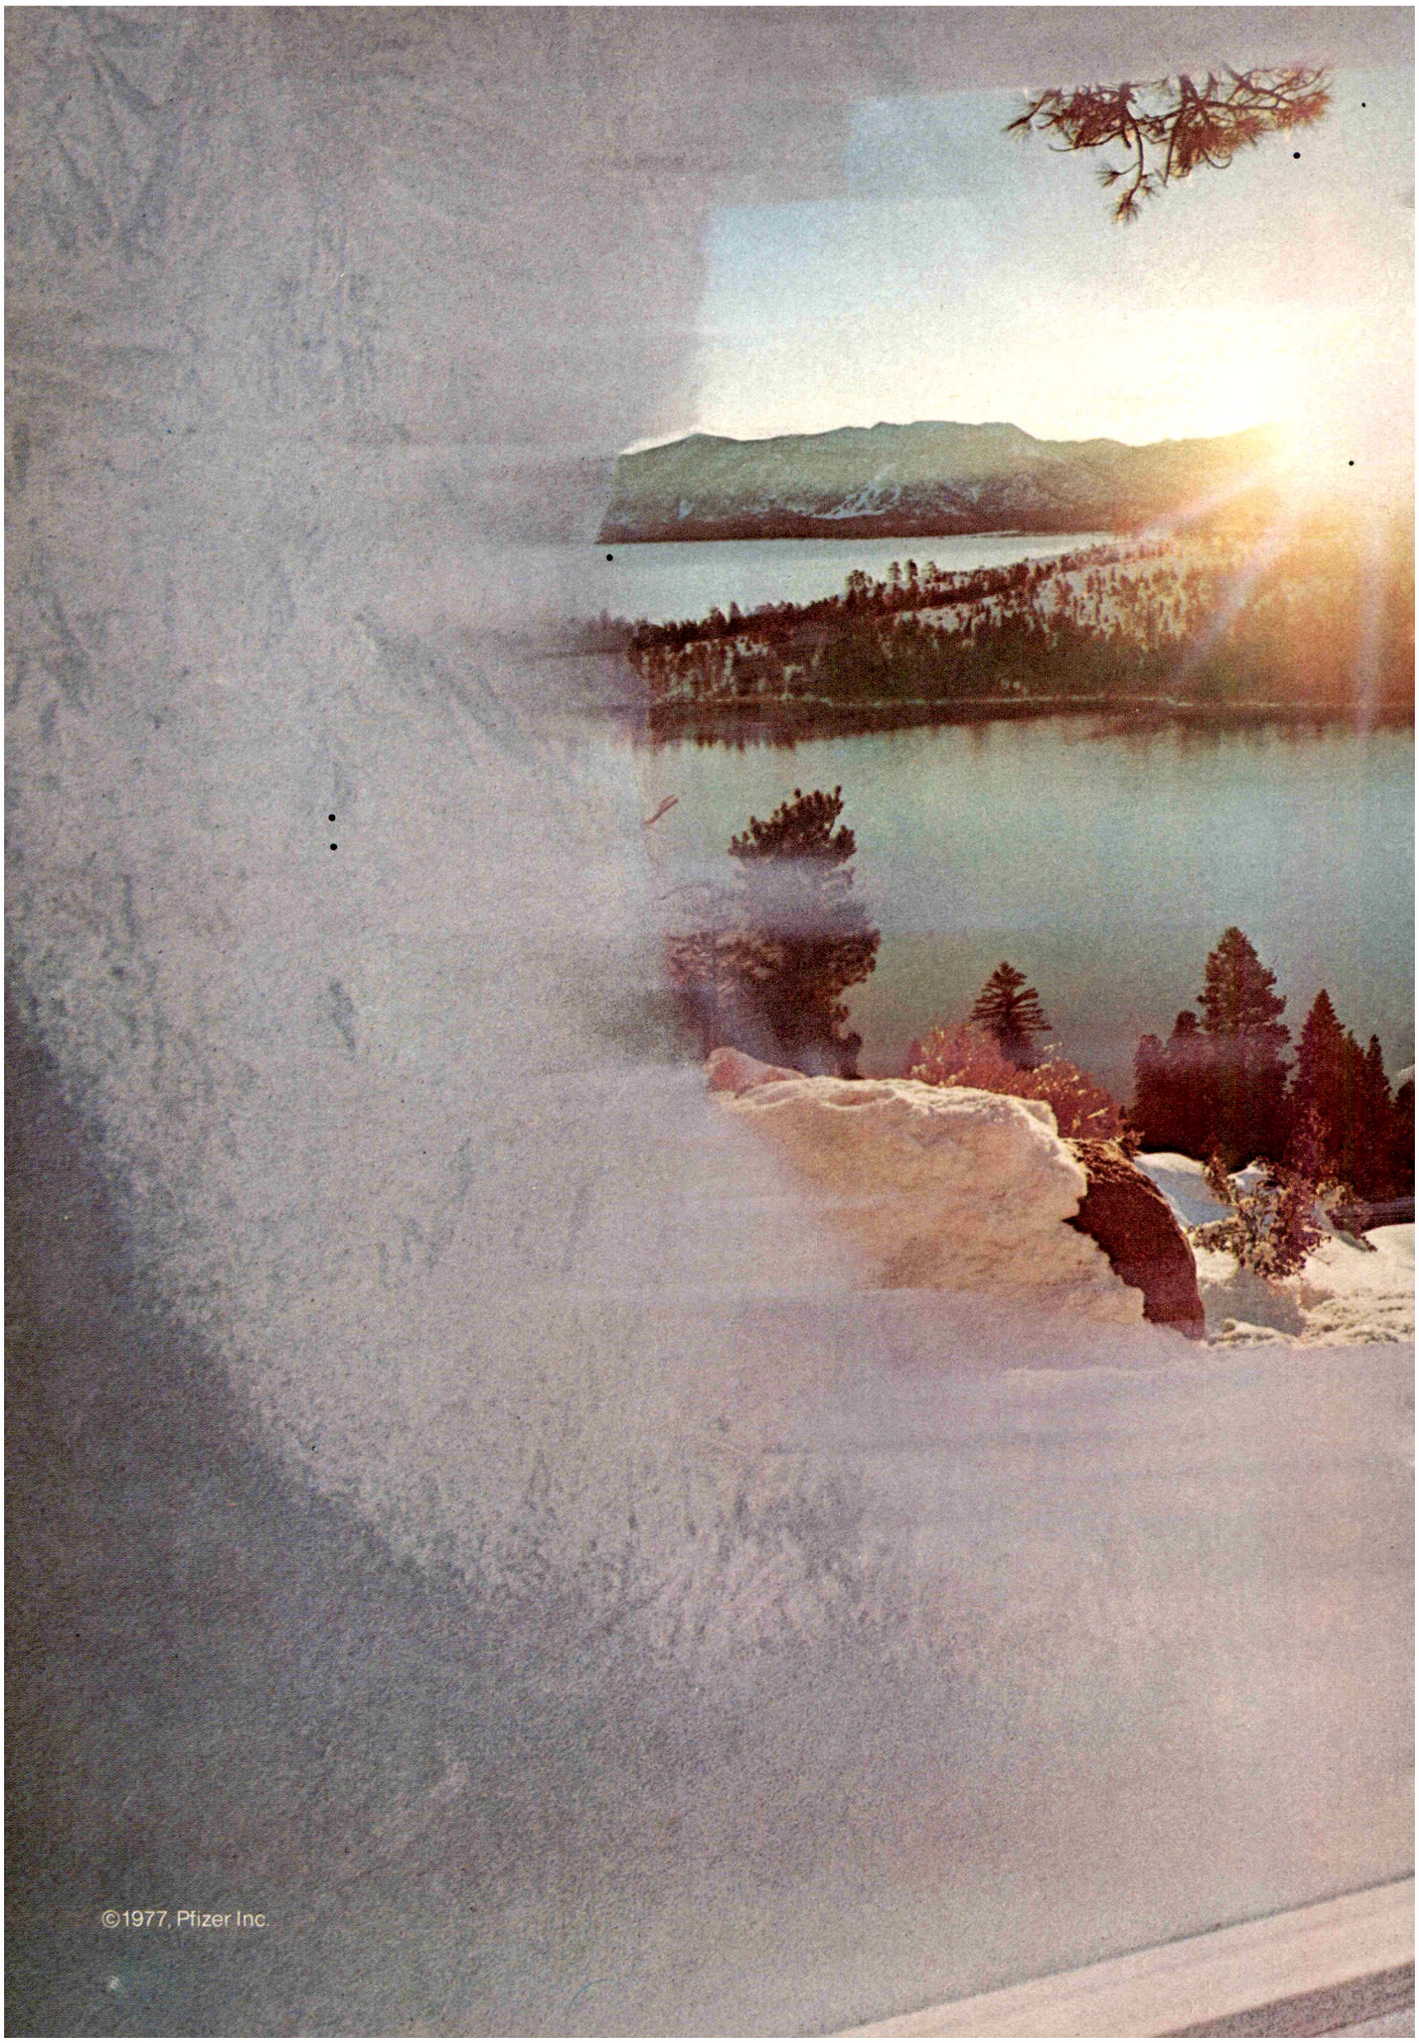
Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**



Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

INTRODUCING
NEW
SINEQUAN® 75 mg
(DOXEPIN HCl) CAPSULE

©1977, Pfizer Inc.

CLEARING OF DEPRESSION
ANTIDEPRESSANT EFFECTIVENESS...
with convenient once-a-day h.s. dosage*
SINEQUAN®
(DOXEPIN HCl)
NEW 75-mg CAPSULE
Also available:
100-mg, 50-mg, 25-mg, 10-mg CAPSULES and
ORAL CONCENTRATE 10 mg/ml, in 120-ml (4-oz) bottles
*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.
See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

IN THE TREATMENT OF CLINICAL DEPRESSION—

NEW SINEQUAN® 75 mg (DOXEPIN HCl) CAPSULE

EXTENDS THE RANGE OF DOSAGE STRENGTHS

PROVIDING ANTIDEPRESSANT EFFECTIVENESS

IN ADDITION TO OTHER, OFTEN BENEFICIAL, PROPERTIES...

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

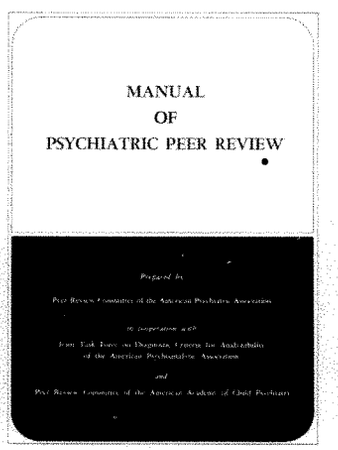
which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY GOOD TOLERATION

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have occasionally been reported. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.



BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate
Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.
Warnings. The once-a-day dosage regimen of SINEQUAN in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.
Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.
Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.
Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.
MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.
Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug. Patients should also be cautioned that their response to alcohol may be potentiated.
Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy.
Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.
Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.
Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.
Central Nervous System Effects. Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.
Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.
Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.
Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.
Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)
Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.
Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.
Dosage and Administration. For most patients with illness of mild to moderate severity, a starting dose of 25 mg t.i.d. is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.
In more severely ill patients an initial dose of 50 mg t.i.d. may be required with subsequent gradual increase to 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg/day.
In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg/day.
As an alternative regimen, the total daily dosage, up to 150 mg, may be given on a once-a-day schedule without loss of effectiveness. This dose may be given at bedtime.
Anti-anxiety effect is apparent before the antidepressant effect. Optimal antidepressant effect may not be evident for two to three weeks.
Overdosage.
A. Signs and Symptoms
1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias and tachycardias.
Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus), hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.
B. Management and Treatment
1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressive supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions to prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbed. The use of activated charcoal has been recommended, as has been continuous gastric lavage with saline for 24 hours or more. An adequate airway should be established in comatose patients and assisted ventilation used if necessary. EKG monitoring may be required for several days, since relapse after apparent recovery has been reported. Arrhythmias should be treated with the appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CNS symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intravenous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine is rapidly metabolized, the dosage should be repeated as required. Convulsions may respond to standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depression. Dialysis and forced diuresis generally are not of value in the management of overdosage due to high tissue and protein binding of SINEQUAN.
Supply. Available as capsules containing doxepin HCl equivalent to 10 mg, 25 mg, 50 mg, 75 mg, and 100 mg doxepin in bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). SINEQUAN 25 mg and 50 mg are also available in bottles of 5000. SINEQUAN Oral Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibrated at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Just prior to administration, SINEQUAN Oral Concentrate should be diluted with approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune or pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number of carbonated beverages. For those patients requiring antidepressant therapy who are on methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mixed together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not with grape juice. Preparation and storage of bulk dilutions is not recommended.

MANUAL OF PSYCHIATRIC PEER REVIEW

by the Peer Review Committee of the American Psychiatric Association, Donald G. Langsley, M.D., Chairperson in cooperation with the Joint Task Force on Diagnostic Criteria for Analyzability of the American Psychoanalytic Association, William Offenkrantz, M.D., Chairperson, and the Peer Review Committee of the American Academy of Child Psychiatry. Larry B. Silver, M.D., Chairperson.

"This Manual provides a set of guidelines for district branches of APA and their peer review committees which should be adapted and modified in terms of local criteria, standards, and practices. The guidelines are not intended to be hard and fast rules. They are screening criteria, and not regulations to control practice. They are so designed that they can be utilized by non-physicians to identify those cases that can profitably be reviewed by psychiatrists serving on peer review committees. This document should be viewed as transitional, subject to revision as experience is gained, and continually updated in response to advances in psychiatric knowledge and changes in patterns of practice. . . . The application of these standards, and refinement through experience must rest with the peer review committees of district branches. . . . It should help them to move ahead in the development of a peer review for American psychiatry."

Robert W. Gibson, M.D.
President

Part I titled PSYCHIATRIC PEER REVIEW contains sections on Basic Relationships and Responsibilities, Appointment of Peer Review Committees, Funding, Operations and Procedures, Medical Care Evaluation Studies, Appeals Processes, Special Problems, Confidentiality, Educational Aspects, Medical Ethics, Advocacy, Interdisciplinary Aspects, with Appendices on Model Screening Format for Inpatient Treatment for Alcoholism, Model Screening Format for Outpatient Treatment, Sample Form for Requesting Extension of Office Treatment, Claims Review Guidelines Suggestions, APA Position Papers on Peer Review, Bibliography.

Part II titled PSYCHOANALYTIC PEER REVIEW has sections on Steps in Peer Review for Psychoanalysis, Guidelines for Model Criteria Sets, Pilot Application of Guidelines for Model Criteria Sets, Sample Peer Review Form, Sample data from Pilot Applications of Guidelines, and Glossary of Terms Used.

Part III titled PEER REVIEW AND CHILD PSYCHIATRY contains sections of Special Considerations, Legal Rights of Children, Issue of Confidentiality, Conclusions, References, and Appendices on Model Screen Criteria Format for Intermediate Care, for Acute Care in a Short Stay Facilities, and for Partial Hospitalization, Outpatient Diagnostic Evaluation Procedures, and Outpatient Treatment for Children and Adolescents.

CASE SUMMARY SHEET

History:	First hospitalization four years ago following divorce. Dx: Acute schizophrenia. Treated with neuroleptics and ECT. On convalescent status, receiving medication through OPD for 18 months. Living with mother, working for past six months
Onset of current illness:	Became depressed when milk route was changed, but did not complain to employer. Developed sleeping problems, had delusions that customers had it "in for him" because of previous mental illness. Hallucinated that ex-wife living out-of-state visited him in his room complaining of money problems. Patient admitted to hospital asking for wife to leave him alone
Diagnosis:	Chronic schizophrenia, acute exacerbation
Treatment:	LOXITANE® C Loxapine Hydrochloride, 75 mg stat, then 50 mg b.i.d. increased over one week to 50 mg q.i.d.
Therapeutic course:	First week, less excited and hyperactive, fewer hallucinations, sleeping better. Second week, questioning reality of delusions and hallucinations, developed stiffness, rigid gait, and masked facies which responded to reduced dosage – 50 mg capsules t.i.d. – and appropriate antiparkinson medication
Follow-up:	4-1/2 weeks: No extrapyramidal symptoms noted. Taking part in OT and PT, relating better but affect still blunted. Planning with social worker for future weekend passes; mother cooperative. Antiparkinson medication discontinued. LOXITANE 50 mg b.i.d.

*Not an actual patient. The collection of clinical data upon which this simulation is built illustrates the action of LOXITANE® Loxapine Succinate as reported in clinical studies.

Loxitane®
LOXAPINE Lederle SUCCINATE

For the symptoms that brought him there

Recommended Daily Dosage

Initial Dosage	MILD 10 mg b.i.d.	MODERATE 10 mg t.i.d. or q.i.d.	SEVERE 25 mg b.i.d.
First 7 to 10 Days	Increase dosage until psychotic symptoms are controlled. Dosage should not exceed 250 mg/day. Usual dosage during titration: 50 to 150 mg/day		
Maintenance Dosage	Adjust to lowest effective level. Usual maintenance dosage: 60 to 100 mg/day Many patients are controlled with dosages as low as 20 to 60 mg/day		

Brief Summary

LOXITANE® Loxapine Succinate Capsules
OR
LOXITANE® C Loxapine Hydrochloride Oral Concentrate

Description: A dibenzoxazepine compound, representing a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines.

Indications: For the manifestations of schizophrenia. Loxapine has not been evaluated for the management of behavioral complications in mental retardation, and therefore cannot be recommended.

Contraindications: In comatose or severe, drug-induced depressed states (alcohol, barbiturates, narcotics, etc.); and in individuals with known hypersensitivity to the drug.

Warnings: In Pregnancy: Safe use during pregnancy or lactation has not been established; in pregnancy, nursing mothers, or women of child-bearing potential, weigh potential benefits against possible hazards to mother and child. No embryotoxicity or teratology was observed in studies in rats, rabbits or dogs, although with the exception of one rabbit study, the highest dosage was only two times the maximum recommended human dose and in some studies they were below this dose. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from mid-pregnancy with doses of 0.6 and 1.8 mg./kg., doses which approximate the usual human dose but which are considerably below the maximum recommended human dose. **In Children:** Studies have not been performed in children; therefore this drug is not for use below the age of 16.

May impair mental and/or physical abilities, especially during the first few days of therapy; warn ambulatory patients about activities requiring alertness (*e.g.*, operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

Precautions: Use with extreme caution in patients with history of convulsive disorders; seizures have been reported in epileptics receiving this drug at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy. Has an antiemetic effect in animals; this effect in man may mask signs of overdosage of toxic drugs and obscure conditions such as intestinal obstruction and brain tumor. Use with caution in patients with cardiovascular disease. Increased pulse rates in the majority of patients receiving antipsychotic doses and transient hypotension have been reported. In hypotension requiring vasopressor therapy, preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine. Possibility of ocular toxicity from loxapine cannot be excluded at this time, therefore observe carefully for pigmentary retinopathy and lenticular pigmentation (observed in some patients receiving certain other antipsychotic drugs for prolonged periods). Because of possible anticholinergic action, use with caution in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinson medication.

Adverse Reactions: CNS: Adverse effects other than extrapyramidal, infrequent. Drowsiness, usually mild, may occur at beginning of therapy or when dosage is increased, usually subsiding with continued therapy. Incidence of sedation is less than that of certain aliphatic phenothiazines and slightly more than piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported. Extrapyramidal reactions during use of this drug have been reported frequently, often during the first few days of treatment. In most patients, these involve Parkinson-like symptoms such as tremor, rigidity, excessive salivation, masked facies, akathisia, usually not severe and controlled by dosage reduction or use of antiparkinson drugs in usual dosage. *Less frequent, but more severe:* Dystonias, including spasms of muscles of neck and face, tongue protrusion, oculogyric movement; dyskinesia in the form of choreo-athetoid movements. These sometimes require reduction or temporary withdrawal of drug dosage in addition to appropriate counteractive drugs. *Persistent Tardive Dyskinesia:* May appear in some patients on long-term therapy, or after therapy has been discontinued; the risk greater in the elderly, especially females, on high dosage. These symptoms, persistent and in some patients apparently irreversible, are characterized by rhythmical involuntary movement of tongue, face, mouth or jaw (*e.g.*, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements, sometimes accompanied by involuntary movements of extremities). No known effective treatment; discontinue all antipsychotic agents if these symptoms appear. The necessity to reinstitute treatment or increase dosage, or switch to a different antipsychotic agent, may mask syndrome. If medication is stopped when fine vermicular movements of the tongue occur, the syndrome may not develop. *Cardiovascular:* Tachycardia, hypotension, hypertension, lightheadedness, syncope. A few cases of EKG changes similar to those seen with phenothiazines have been reported, not known to be related to loxapine use. *Skin:* Dermatitis, edema (puffiness of face), pruritus, seborrhea. Possible photosensitivity and/or phototoxicity; skin rashes of uncertain etiology seen in a few patients during hot summer months. *Anticholinergic:* Dry mouth, nasal congestion, constipation, blurred vision—more likely to occur with concomitant use of antiparkinson agents. *Other:* Nausea, vomiting, weight gain or loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, polydipsia. Rarely, galactorrhea and menstrual irregularity of uncertain etiology.

Dosage and Administration: Administered orally, usually in 2 to 4 divided doses a day. Adjust dosage to patient's need relative to severity of symptoms and history of response to antipsychotic drugs. Recommended initial dosage is 10 mg. b.i.d.; in severely disturbed patients up to 50 mg. daily. Increase dosage during first 7 to 10 days until psychotic symptoms are controlled. Usual therapeutic and maintenance range is 60 mg.-100 mg. daily. More than 250 mg. daily is not recommended. Maintenance dosage should be at lowest level to control symptoms; many patients have been maintained on 20 mg. to 60 mg. daily.

LOXITANE C Oral Concentrate should be mixed with orange and grapefruit juice shortly before administration. Use only enclosed calibrated dropper.

SANDOZ
SAN 6-640R

ANTIPSYCHOTIC EFFICACY... INFREQUENT EXTRAPYRAMIDAL SYMPTOMS

Antipsychotic medication should not interfere with the patient's ability to participate in your total therapeutic program. That is why Mellaril (thioridazine) is an excellent choice. It is highly effective, and although extrapyramidal symptoms are characteristic of this class of drug, with Mellaril (thioridazine) extrapyramidal stimulation—notably pseudoparkinsonism—is infrequent. Adding an antiparkinsonian agent—which can cause its own side effects—can usually be avoided.

Mellaril (thioridazine) is not habituating and usually does not cause euphoria or undue sedation. (But, warn patients about undertaking activities requiring complete mental alertness.) And Mellaril (thioridazine) is contraindicated in patients with severe hypotensive or hypertensive heart disease.

MELLARIL® (THIORIDAZINE)

TABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

THE AMERICAN JOURNAL OF PSYCHIATRY

Psychotherapies: An Overview

BY TOKSOZ B. KARASU, M.D.

The author schematically describes the three predominating themes in the development of the psychotherapies: dynamic, behavioral, and experiential. These themes represent different conceptualizations of the fundamental nature of man and his ills, therapeutic processes or change agents, the basic nature of the physician-patient relationship, and the primary techniques and methods used. Although there appears to be some unifying thread connecting the four different areas within each theme, a comparable bond does not exist across the three themes. The author questions the potential unification of the psychotherapies and poses specific dimensions for further exploration.

THE EMERGENCE of numerous competing systems of psychotherapy during the last few decades has been cited as one of the principal problem areas in the field (1). In 1975 Parloff polled more than 140 presumable forms of currently practiced psychotherapy (2). Although London described this confusing proliferation as a reflection of changing times in answer to pervasive repression, anxiety, and/or boredom of man (3), the specific ways in which each new modality may or may not differ from its predecessors are far from clear. For the most part, dogmatic partisan claims of the superiority of each successive system continue to persist in spite of increasing evidence that such separatist claims may be largely unfounded (4, 5).

In attempts to comprehend the therapeutic influence in the total range of psychological treatments that have made their appearance at various points in the course of time, many authors have focused on the nonspecific or common elements that all psychotherapies are presumed to share (4, 6–19). The following features have been repeatedly cited as basic to all psychotherapies: an emotionally charged, confiding relationship; a therapeutic rationale (myth) that is accepted by patient and therapist; the provision of new information, which may be transmitted by precept, example, and/or self-discovery; the strengthening of the patient's expectation of help; the provision of success experiences; and the facilitation of the arousal of one's emotions (9).

Alternatively, Wittkower and Warnes pointed out that "while such universal features undoubtedly exist, it seems absurd to minimize differences in psychotherapy" (19). The originators and strong proponents of individual systems of psychotherapy who felt the need to differentiate and/or disassociate themselves from their predecessors and peers to justify their efforts might share this view (20–23). In addition, comparative conceptual studies of various forms of psychotherapy typically cite striking contrasts among various therapies (24–33). More recently, experimental studies of different schools have lent some scientific support to the separatist stance. Exemplary of such findings are the systematic studies of analytically oriented psychotherapy versus behavior therapy supporting the view that these are, in total, highly contrasting styles of treatment (34, 35). Moreover, the treatment procedures created, developed, and chosen in one society or within the context of a particular belief system may not be transposable to another. This is especially evident in attempts at cross-cultural psychotherapy (19, 36).

The current state of the art attests to the lack of clarity and lack of resolution of the specificity versus common elements controversy in explaining what is the quintessence of the therapeutic cure. This conflicting state of affairs is further compounded by those comparative studies of various psychotherapies which suggest that one's espoused theoretical orientation regarding the nature of the healing process may not always be synchronous with one's actual practices (37–39). For example, a comparison study of Freudian,

Dr. Karasu is Associate Professor of Psychiatry and Vice-Chairman, Department of Psychiatry, Albert Einstein College of Medicine, and Director, Department of Psychiatry, Bronx Municipal Hospital Center, Pelham Parkway South and Eastchester Rd., Bronx, N.Y. 10461.

TABLE 1
Examples of Three Therapeutic Themes in the Psychotherapies and Their Variations*

Dynamic		Behavioral		Experiential	
Theme or Variation	Representative	Theme or Variation	Representative	Theme or Variation	Representative
Classical psychoanalysis	Freud	Reciprocal inhibition therapy	Wolpe	Existential analysis	Binswanger
Analytical psychology	Jung	Implosive therapy	Stampfl	Daseinanalysis	Boss
Will therapy	Rank	Conditioned reflex therapy	Salter	Logotherapy	Frankl
Active analytical therapy	Stekel	Learning theory therapy	Dollard	Client-centered therapy	Rogers
Individual psychology	Adler	Social learning psychotherapy	Rotter	Gestalt therapy	Perls
Interpersonal psychiatry	Sullivan	Modeling therapy	Bandura	Psycho-imagination therapy	Shorr
Intensive psychotherapy	Fromm-Reichmann	Directive psychotherapy	Thorne	Experiential therapy	Whitaker
Character analysis	Horney	Direct decision therapy	Greenwald	Experiential therapy	Gendlin
Cultural school	Fromm	Confrontation problem solving	Garner	Primal scream therapy	Janov
Ego analysis	Klein	Assertion-structured therapy	Phillips	Bioenergetic analysis	Lowen
Chicago school	Alexander, French	Personal construct therapy	Kelly	Structural analysis	Rolf
Sector therapy	Deutsch	Rational therapy	Ellis	Autogenic training	Luthe
Objective psychotherapy	Karpman	Integrity therapy	Drakeford	Transcendental Meditation	
Short-term psychotherapy	Sifneos, Malan, Bellak	Reality therapy	Glasser	Nirvana therapy	
Direct analysis	Rosen	Philosophical psychotherapy	Sahakian	Zen psychotherapy	Watts
Psychobiological therapy	Meyer	Biofeedback training	Green	Psychedelic therapy	Osmond
Biodynamic therapy	Masserman				
Adaptational psychodynamics	Rado				
Hypnoanalysis	Wolberg				
Character analysis, vegetotherapy	Reich				

*Although some of the more recent psychotherapies may combine individual and group techniques, this organization of psychotherapeutic systems focuses on modalities that are essentially dyadic in nature. It therefore does not include family, group, or milieu therapies per se, nor such adjunct therapies as art, music, and dance.

Kleinian, Jungian, and Gestaltist therapists found that descriptive ratings of the different approaches in action did not differentiate the respective schools of thought as well as the investigators (and, no doubt, the proponents themselves) would have expected (39).

As treatments useful in one area of human disturbance are found to be less valuable in another (5, 40), efforts are made to arrive at better criteria for selecting patients for particular forms of therapy and for modifying existing forms. Here the stated task for the future is to achieve greater specificity concerning the effects of particular kinds of interventions (13). Thus the tantalizing need for increased examination and clarification of the therapeutic process continues.

Doubtless there are many ways to slice the therapeutic pie. In early attempts to schematize the many psychotherapeutic methods and techniques throughout history, Menninger (41) and Bromberg (42) ultimately subsumed the various forms under two dichotomous heads: those which they thought used a principle of suppression in their treatment approach versus those which represented the use of a principle of expression.

Beginning where Menninger and Bromberg left off, Harper's descriptive overview of 36 established Freudian and post-Freudian psychotherapeutic schools, or systems of psychotherapy, attempted to divide the various approaches into two overriding categories: those which reflected emotionally oriented or affective forms of treatment versus those which Harper considered essentially intellectually oriented or cognitive (28). On a more philosophical plane, Rychlak addressed the possible implications of ideology for methodology and assessed psychotherapies on the basis of whether they represented therapeutic models that were essentially Lockean (mechanistic) or Kantian (humanistic) (43). Rychlak also conceptualized psychotherapies according to a comparison of their respective motives: those with a scholarly motive, which are primarily concerned with unraveling the depths of

TABLE 2
Summary of Thematic Dimensions of Three Kinds of Psychotherapy

Theme	Dynamic	Behavioral	Experiential
Prime concern	Sexual repression	Anxiety	Alienation
Concept of pathology	Instinctual conflicts: early libidinal drives and wishes that remain out of awareness, i.e., unconscious	Learned habits: excess or deficit behaviors that have been environmentally reinforced	Existential despair: human loss of possibilities, fragmentation of self, lack of congruence with one's experiences
Concept of health	Resolution of underlying conflicts: victory of ego over id, i.e., ego strength	Symptom removal: absence of specific symptom and/or reduction of anxiety	Actualization of potential: self-growth, authenticity, and spontaneity
Mode of change	Depth insight: understanding of the early past, i.e., intellectual-emotional knowledge	Direct learning: behaving in the current present, i.e., action or performance	Immediate experiencing: sensing or feeling in the immediate moment, i.e., spontaneous expression of experience
Time approach and focus	Historical: subjective past	Nonhistorical: objective present	Ahistorical: phenomenological moment
Type of treatment	Long-term and intense	Short-term and not intense	Short-term and intense
Therapist's task	To comprehend unconscious mental content and its historical and hidden meanings	To program, reward, inhibit, or shape specific behavioral responses to anxiety-producing stimuli	To interact in a mutually accepting atmosphere for arousal of self-expression (from somatic to spiritual)
Primary tools techniques	Interpretation: free association, analysis of transference, resistance, slips, and dreams	Conditioning: systematic desensitization, positive and negative reinforcements, shaping	Encounter: shared dialogue, experiments or games, dramatization or playing out of feelings
Treatment model	Medical: doctor-patient or parent-infant (authoritarian), i.e., therapeutic alliance	Educational: teacher-student or parent-child (authoritarian), i.e., learning alliance	Existential: human peer-human peer or adult-adult (egalitarian), i.e., human alliance
Nature of relationship to cure	Transferential and primary for cure: unreal relationship	Real but secondary for cure: no relationship	Real and primary for cure: real relationship
Therapist's role and stance	Interpreter-reflector: indirect, dispassionate, or frustrating	Shaper-adviser: direct, problem-solving, or practical	Interactor-acceptor: mutually permissive or gratifying

man's nature; those with an ethical motive, which concern themselves primarily with man's self and his values; and those with a curative motive, which directly aim at scientifically derived cure (44). Offenkrantz and Tobin's configuration is more implicit. They suggested that all learning (including psychotherapeutic learning) occurs in three modes: by identification, by conditioning, and by insight (45). Thus one might assume to unite the various psychotherapies on the basis of their primary modes of therapeutic learning or the major ways in which they presume to effect change in or cure of the patient.

With the preceding topographies in mind, I shall organize the morass of systems practiced today according to a troika of basic themes around which each school may be said to broadly, but distinctively, pivot. These, representing a composite of dimensions, are referred to as dynamic, behavioral, and experiential (see table 1). Although these rubrics per se are not completely new (2, 46), to my knowledge no study has attempted to portray schematically their respective features in relation to the increasing array of modalities being practiced today. A number of contrasting dimensions constitute or reside behind these three themes (see table 2). Each theme represents something of a unity, that is, one's conceptual framework or belief system regarding the nature of man and his ills will have a bearing on one's concept of therapeutic modes or curative processes and the nature of the therapeutic relationship between patient and therapist and, ultimately, on one's methods or techniques of treatment.

THE DYNAMIC THEME

The Nature of Man and His Ills

The dynamic point of view, as originally conceived in the context of physics, subscribes to the idea that all mental phenomena are the result of an interaction of forces (47). It pertains to an appreciation of the complexity of man as reactor to or victim of turbulent intrapsychic forces from which he continually struggles to be set free. Freud described the major force of this struggle in the origin of the neuroses of man according

to the theory of instinctual conflict: "From the very first we have said that human beings fall ill of a conflict between the claims of instinctual life and the resistance which arises within them against it" (48, p. 57). More specifically, Freud considered the etiology of the neuroses of man to be decidedly sexual in nature: "No neurosis is possible with a normal *vita sexualis*" (49, p. 276). In the orthodox dynamic tradition man is portrayed as fraught with inner and unknown urgings and contradictions, subject to and resisting against a reservoir of impulses largely inaccessible to his conscious self.

The psychoanalytic perspective typically incorporates five fundamental principles, i.e., dynamic, economic, structural, developmental, and adaptive (50). Taken together, these principles offer an analytic legacy that includes the following allegiances: 1) a primary concern with the vicissitudes of man's instinctual impulses, their expression and transformation, and, more crucially, their repression, by which is meant the pervasive avoidance of painful feelings or experiences by keeping unpleasant thoughts, wishes, and affect from awareness; 2) the belief that such repression is of an essentially sexual nature and that the roots of disturbance reside in faulty libidinal or psychosexual development; 3) the idea that faulty psychosexual development has its origins in early past and childhood conflicts or traumata, especially those concerning a parental oedipal configuration as manifested in the classic desire for one's opposite-sexed parent; 4) the belief in the resilience, persistance, and inaccessibility of oedipal yearnings (i.e., these underlying conflicts remain alive and ever active but out of awareness or unconscious; man's consciousness describes the exceptional rather than the standard state of affairs); 5) the idea that we are dealing essentially with the psychic struggle and torments of biological man's innate impulses or instincts (id), their derivatives, and the primarily defensive mediation with external reality (ego) in light of one's moral precepts or standards (superego); and, finally, 6) an adherence to a concept of psychic determinism or causality according to which mental phenomena as well as behaviors are decidedly not chance occurrences but meaningfully related to events that preceded them and, unless made conscious, unwittingly subject to repetition.

Therapeutic Change or Curative Processes

In accordance with these tenets, for the dynamic therapist the ultimate task in its most parsimonious and famous form is to make conscious the unconscious. This means that it is the ongoing therapeutic charge of the therapist who subscribes to the dynamic view to facilitate the emergence and comprehension of unconscious and largely libidinal content. That is, the dynamic therapist seeks to undo the essentially sexual repression of the patient and to overcome the patient's natural resistances to this endeavor. The dynamic therapist attempts to accomplish this by means of a slow and scrupulous unraveling of the largely historical meanings of mental events and the devious ways in which they may serve to ward off the underlying conflicts through defensive camouflage. Understandably, the dynamic goal is thereby a long-range one, perhaps even interminable. At best this concept of cure means opting for total personality reorganization in the final resolution of neurotic conflicts. The most crucial manifestation of this is the resolution of the oedipal conflict, which is traditionally regarded as requisite for a healthy personality. This ultimate integration of personality would translate itself into final mastery of ego over id impulses or, as classically stated, where id was, there ego shall be.

Greenson defined the therapeutic process as "an interrelated series of psychic events within the patient, a continuity of psychic forces which have a remedial aim or effect" (51, p.7). The dynamic psychotherapeutic systems have consecutively considered as their hallmarks of change the processes of catharsis (following abreaction) and insight. Harper broadly defined insight as "the process by which the meaning, significance, pattern, or use of an experience becomes clear—or the understanding which results from this process" (28, p.163). He defined catharsis as "the release of tension and *anxiety* by recounting and/or *acting out* past experiences" (28, p.158; author's italics).

Although both processes have been considered in the psychodynamic tradition, it may be noted that Freud never used the term "insight" per se. The therapeutic process transferred its emphasis from the primary importance of abreaction (catharsis) to the removal of amnesia and the recovery of repressed memories. Following this shift, Greenson pointed out, "catharsis [is] no longer the ultimate aim of therapy" (51, p.13). In its stead, the process of insight has been extensively singled out not only to refer to a phenomenon specially applicable to the psychodynamic therapies in contrast to other therapies (51–53) but also as the patient's ultimate aspiration.

According to Hutchinson, there are four successive stages in attaining therapeutic insight: 1) a stage of preparation, which is characterized by frustration, anxiety, a feeling of ineptness, and despair and may be followed by much trial-and-error activity relevant to the solution of a certain problem and the falling into habitual patterns or ways of thinking, foreseeing no apparent solution to the problem; 2) a stage of incubation or renunciation in which one desires to hide or escape from the problem and one is resistant or unmotivated in therapeutic or insightful efforts; 3) a stage of inspiration or illumination in which the whole problem becomes illuminated and a solution or solutions suggest themselves (often there is a flood of vivid ideas and a sense of finality accompanied by a conviction in the truth of the insight); and 4) a stage of elaboration and evaluation in which the validity of the insight is checked against external reality (54).

Although the third stage tends to be most frequently identified with the idea of insight (suggesting an essentially eureka phenomenon), Ludwig pointed out that

> during the typical course of psychotherapy, it is much more common for the patient to experience insight in a . . . drawn out and emotionally attenuated from. The sudden tidal wave of illumination or enlightenment is rare compared to the numerous small ripples of insights which are experienced and intellectually assimilated over a long period of time. Moreover, the therapeutic insights tend to be circumscribed and specific to certain problem areas than the profound and general eureka experiences, such as those described to occur during religious conversion or revelation in which the "whole truth" suddenly is revealed. (55, p. 315)

In terms of the therapeutic value of the process of insight, Ludwig noted that "there is no necessary relationship between the truth or falseness of insight and therapeutic results" (55, p. 313). In addition, since intellectual insight alone is felt to be of minimal value, attempts have been made to distinguish between intellectual and emotional insight. However, it is difficult to validate such a distinction (56).

In brief, Ludwig hypothesized that insight is therapeutic when it meets all of the following specifications: 1) consistency, that is, the deductions based on the original insight are stable and logically sound regardless of the truth or falsity of the particular content of the insight; 2) continuity, that is, insights must take place within some existing theoretical framework or stream of tradition in which the insight can be tested; 3) personal consequences, that is, the insight must be judged by the fruit it bears in terms of the ultimate use to which the insight is put; and 4) social consequences, that is, the acquisition of insight should allow the person to interact with others in a more honest and meaningful manner (55).

Although analysts have confidence in the role of insight as a therapeutic agent, doubt has been cast on the "insight leads to change" dictum. Schonbar, for example, has observed that "not all change is attributable to insight" and "not all insight leads to change" (57). However, the fact that insight, even as an ultimate change agent, does not occur in isolation is more important for consideration of the analytic therapies. Intricately embedded in the psychodynamic curative process is the critical role of the therapeutic relationship, expressly manifested in the phenomenon of the transference relationship.

The Nature of the Therapeutic Relationship

In 1970 Strupp noted, "There can be no doubt that the patient's relationship to the therapist . . . embodies one of the most powerful forces in the therapeutic enterprise. . . . Psychotherapeutic changes always occur in the context of an interpersonal relationship, and are to some extent inextricable from it" (13, pp. 396, 400). The specific therapeutic agent, according to Rosen, seems to be the "complex, emotionally-charged parent-child kind of relationship between the psychiatrist and the individual whom he is treating" (58, p.126). In terms of the special nature of that therapeutic relationship, it should be pointed out that deliberate systematic attention to the vicissitudes of the special relationship between therapist and patient is crucial to the conduct of the psychoanalytic psychotherapies. It constitutes both the subject and the object of analysis.

Historically, two roles or stances for the therapist have been described in portraying the psychodynamic psychotherapies: the primary stance with regard to the making of the transference relationship and, more recently, the secondary stance with regard to the making of a working or therapeutic alliance. Despite increasing acceptance of the latter into the therapeutic situation, these represent dual postures, which Greenson explicitly depicted as antithetical to each other, both in their essential purposes and in the actual requirements they make of the therapist (51).

The primary stance reflects Freud's original recommendations 1) that the analyst be like a mirror to the patient, reflecting only what is reflected to him/her by the patient and not bringing his/her own feelings (attitudes, values, personal life) into play (59) and 2) that the analyst follow a posture of privation or rule of abstinence, that is, technical motives must unite with ethical ones in preventing the therapist from offering the patient the "love" that the patient will necessarily come to crave (59, pp. 157–171).

These dictums have been taken to mean that two basic requirements are traditionally made of the analyst if he/she is to best accomplish the therapeutic task: 1) he/she must continue to judiciously frustrate and avoid gratifying the wishes of the patient; and 2) he/she must remain relatively removed and anonymous, a deliberately dispassionate observer and reflector of the patient's feelings. The therapeutic relationship is asymmetrical. Henry and associates described the relationship as follows:

> Only the patient is supposed to reveal the intimate details of his life. The psychotherapist is not only free to determine what he will reveal and conceal about himself, but also to choose how to react to what the patient is saying, if indeed he decides to respond at all. The relationship is also asymmetrical in that only the therapist is supposed to interpret and impute meaning to what the patient is saying and only the therapist can evaluate the degree to which therapeutic objectives are being achieved in the relationship. (60, p. 218)

Conversely, within the same framework, the more recent concept of a working or therapeutic alliance reflects an alternatively nonregressive, rational relationship between patient and therapist. Although still in the service of analyzing transference and resistances, according to Chessick it means "that the therapist aims at forming a real and mature alliance with the conscious adult ego of the patient and encourages him to be a scientific partner in the exploration of his difficulties" (53). The real object need of the patient, deliberately frustrated by the transference relationship, is satisfied by the therapeutic alliance.

Techniques and Methods

Bellis' statement that "no technique is therapeutic in itself. . . . Every clinician must understand and calibrate his own instruments" (61) bears repeating in a discussion of the techniques of dynamic psychotherapy.

The major instruments of the prototypic dynamic approach are primarily verbal in nature. They rest in part on the proverbial talking cure and may be regarded as free association on the part of the patient and analysis of transference reactions and resistances on the part of the therapist. Analysis, the task of the therapist, is facilitated by four specific procedures: confrontation, clarification, interpretation, and working-through. It is the third of these, interpretation, that, according to Greenson, is regarded as the "ultimate and decisive instrument" (51).

With regard to the input of the patient, the technique of free association early reflected the major vehicle for the communication of uncensored content from patient to therapist. It has constituted the primary procedure for eliciting the raw material on which the analysis ultimately rests. This includes the eliciting of dreams, which Freud regarded as "the royal road to a knowledge of the unconscious activities of the mind" (62, p. 608). Methodologically, the attempt to solicit free associations and dreams from the patient accounts for the most notorious material ingredient of the analytic method in classical analysis—the couch. Having the patient in a supine position out of direct view of the therapist and without extrinsic environmental intrusions is meant to create conditions of relative sensory deprivation that in turn serve to maximize the evocation of repressed memories.

With regard to the therapist's task and response to the verbal material elicited from the patient, the crux of the psychoanalytic method remains the analysis of transference, which comprises the major instrument of analysis as well as its major obstacle. The deliberate elucidation of transference reactions results in inevitable resistances to this endeavor, which must also be overcome as part of the treatment. Methodologically, the reflective, ambiguous stance of the therapist in concert with the high frequency and regularity of contacts between patient and therapist are meant to encourage the regressive transference process and the intensity of feelings in the treatment situation.

Despite the endowment of the value of interpretation, the therapeutic path must be carefully paved in order for it to have its most beneficial effects. In this regard, the role of the techniques of confrontation, clarification, and working-through have been noted. Confrontation refers to having the patient discern or face the particular mental event to be investigated: clarification refers to placing the same event in sharp focus, separating important aspects from insignificant ones (both of these processes prepare for the actual interpretation); interpretation then goes beyond the manifest material by assigning an underlying meaning or cause to the event or phenomenon in question; finally, working-through refers to the repetitive, progressive, and elaborate explorations of the interpretations and resistances to them until the presented material has become fully integrated into the patient's understanding. This is perhaps the most time-consuming aspect of dynamic psychotherapy. Although the major thrust of treatment occurs within the therapist's office, working-through necessarily includes the tacit work done by the patient outside of the therapeutic hour.

In terms of comparisons with other forms of treatment and their reputed curing powers, certain techniques or procedures are considered to be expressly anti-analytic, i.e., to block or lessen one's understanding or insight rather than facilitating it. Foremost in this regard are (perhaps ironically) abreaction, which may still be used but is not felt to directly bring insight; direct suggestion or advice, which is only useful to the extent that it is openly acknowledged and analyzed within the therapy setting; manipulation, allowable only to the extent that it can be brought into the analytic arena and does not occur without the ultimate knowledge of the patient; and the deliberate or conscious assumption of roles or attitudes that create an unanalyzable situation by their very nature.

Variations on the Dynamic Theme

The prototypic embodiment of the psychodynamic theme is, of course, classical psychoanalysis. The variations on the dynamic theme reflect overt and covert modifications of theoretical conceptualizations as well as methodological and technical applications in practice. These include attempts to partially or completely transcend the biological focus of Freud with more interpersonal, social, ethical, and cultural considerations (e.g., Adler, Horney, Sullivan, Fromm, Fromm-Reichmann, Meyer, and Masserman); to extend or enhance the ego with earlier or more adaptive endowments (e.g., Federn and Klein); to enlarge man's temporality with a time focus on his primordial past (e.g., Jung), his present, and/or his future (e.g., Adler, Stekel, Rank, and Rado); to expand treatment procedures by altering the range and goals of treatment (e.g., Rank, Alexander, Deutsch, and Karpman); to develop guidelines for short-term psychotherapy with anxiety-provoking techniques (e.g., Sifneos) and even brief treatment of serious illness within the context of a single interview (e.g., Malan) (63–67); to revise the role of the therapist's personality and relationship to the patient by making the therapist a more direct, flexible, and/or active participant (e.g., Adler, Sullivan, Rank, Alexander, Stekel, Ferenczi, and Rosen); and, at perhaps the opposing end of the analytic spectrum, to restore the psychophysical balance of man by focusing equally on the physical half of the psychophysical split (e.g., Rado and Masserman) and/or substituting an approach to therapeutic cure from the somatic side by trading the traditional change mode of insight for a reversal back to the earlier ca-

tharsis by means of the bodily release of conflictual tensions (e.g., Reich).

THE BEHAVIORAL THEME

The Nature of Man and His Ills

The behavioral theme presumes that all behavior, both normal and abnormal, is a product of what man has learned or not learned. Neuroses or neurotic symptoms are construed as simple learned habits, involuntarily acquired, repeated, reinforced responses to specific stimuli in the environment. Indeed, Eysenck said, "there is no neurosis underlying the symptom, but merely the symptom itself" (68). Conversely, since external behaviors constitute the essence of the therapeutic problem, the therapeutic cure is simple: "Get rid of the symptom and you have eliminated neurosis" (68).

Behavioral psychotherapy is an outgrowth of animal laboratory experiments on classically conditioned responses in which animals were observed to have habits that were like human phobias. Traditionally, behavioral psychotherapy also presumes that human neuroses have the same basic vicissitudes as those of the animal, in which anxiety (equated with fear) is regarded as its central manifestation (69).

Thus behavioral man is reducible to stimulus-response connections that can be isolated and altered in a piecemeal manner by reinserting new associations. Viewed in this way, behavioral man is infinitely manipulable and therefore controllable by external events in the environment.

The prototype of orthodox behavior therapy is exemplified in Wolpe's reciprocal inhibition therapy, which is based on a classical conditioning paradigm.[1] Wolpe's main thesis is that neurotic symptoms are all essentially phobias based on the adverse learning of unrealistic fears. In behavioral theory this means that anxiety has been conditioned during highly disturbing or traumatic experiences. Wolpe would regard a complex symptom like neurotic passivity as a learned fear of rejection or disapproval reflecting one form of a phobic or anxious reaction to others.

Therapeutic or Change Processes

For the behaviorist all problems are construed as pedagogical in nature and therefore alterable only through direct teaching and learning of new behavioral associations, i.e., stimulus-response connections. The patient must be taught new alternatives that must be repeated and practiced within as well as outside of the therapy situation. These alternative modes of functioning do not occur simply as a concomitant of cognitive or emotional understanding of one's problems; the patient must rehearse the new alternatives directly. Thus, in direct contrast to the psychodynamic schools, the behavioral approaches, according to Cautela, tend to sustain the view that insight is not only unnecessary but usually hinders the treatment for deviant behavior (70). Wolpe's principle of reciprocal inhibition implies the rejection of catharsis as well. Wolpe sees abreaction (the symbolic re-evocation of a fearful past experience) as a special case in point, asserting that no permanent effects are achieved if unrelieved terror is the only emotional factor involved and is not counterposed by relaxation responses.

One implication of this view of the mode of therapeutic change is that change can presumably occur within a short period of time. In contrast to the dynamic theme, Eysenck stated that "all treatment of neurotic disorders is concerned with habits existing in the present; their historical development is largely irrelevant" (68). Moreover, Cautela stated, "In fact, it is possible to have a situation in which symptoms have been removed with no knowledge at all of the etiology" (70).

Although all behaviorists may be viewed as seeking change through direct conditioning, shaping, or training, Wolpe, in accordance with his classical conditioning paradigm, sees all therapeutic learning or change (not just behavior therapy) as occurring within the reciprocal inhibition framework per se. All therapies necessarily incorporate the substitution of relaxation for anxiety in the reduction or elimination of symptoms. However, more critically, the difference between behavior therapy and other therapeutic situations is that in the latter, counterconditioning of relaxation over anxiety occurs fortuitously or unsystematically, whereas in behavior therapy this process is overt, systematic, and under the direct control of the therapist.

The Nature of the Therapeutic Relationship

The nature of the therapeutic relationship between therapist and patient in the behavioral therapies is, according to Hollander, an essentially "educative, teacher-pupil relationship" (71). In contrast to the psychodynamic transferential relationship but comparable to the working or therapeutic alliance in certain respects, the behavioral relationship may be portrayed as a deliberately structured learning alliance, in which, at its best, attention is drawn to the more current and presumably constructive aspects of the patient's personality in collaborating on the course of therapy.

Krasner depicted the behavior therapist as a learning technician or "social reinforcement machine" (72). Although this rubric may apply to all therapies to greater or lesser degrees, usually the behavioral therapist openly regards himself/herself as an instrument of direct behavioral influence or control, one who directly and systematically manipulates, shapes, and/or inserts his/her own values in the therapeutic encounter. In a comparable context, the thera-

[1]The terms "classical" versus "operant" conditioning procedures refer essentially to the respective sequence in the application of the stimulus. In classical conditioning the stimulus precedes and in operant conditioning the stimulus follows the behavioral response to be changed.

pist shapes his/her own behavior so as to be a social reinforcer for the patient. If the therapy does not proceed smoothly or effectively, the behavior therapist revises the behavioral plan or schedule to better fit the patient to treatment (71).

Behavior therapy deliberately does not dwell on the therapist-patient relationship; at most, it does so secondarily, that is, according to APA's Task Force on Behavior Therapy, "only to the extent that this is seen to be important in securing the patient's cooperation with the therapist's treatment plan" (73, p. 27).

The behavior therapist's use of warmth, acceptance, and any other relationship skills is common but relegated to the realm of secondary "relationship skills" that are not crucial therapeutic requirements for desired change to occur in the patient (71).

Techniques and Methods

In Ehrenwald's words, the behavioral schools of psychotherapy actively relinquish "the methods of the couch" and replace them with "the methods of the classroom and the pulpit" (7). The behavior therapist has at his/her disposal a large variety of conditioning, training, and other directive techniques. This repertoire may include any or all of the following: the more classical conditioning techniques of systematic desensitization combined with deep muscle relaxation, implosion, or assertiveness training; the operant techniques of positive or negative reinforcement; aversiveness training; shaping or modeling; and/or the more flexible directive techniques pertaining to the direct transmission of advice, guidance, persuasion, and exhortation. The latter methods more typically reflect the means by which behavior modification has been extended recently to the teaching or conditioning of cognitive behaviors or attitudes underlying specific behaviors, methods of philosophical indoctrination, or cognitive programming.

More generally, the behaviorist initially sets out to identify the patient's specific target behaviors or responses that need to be modified. These, in conjunction with the stimuli or environmental situations that give rise to the specific behaviors, constitute a behavioral formulation that may be regarded as the behaviorist's counterpart of psychodynamic formulation. The behavioral formulation is used for the purpose of setting specific treatment goals, which are usually made explicit to the patient at the outset. The initial interview typically aims to specify what situations or factors contribute to the maintenance of the particular responses in question and on what occasions those responses are most likely elicited. On this basis the behavioral conditioning program can then begin.

Wolpe's classical reciprocal inhibition therapy, which has as its direct aim the reduction or inhibition of anxiety responses through the substitution of relaxation responses for anxiety, typically uses two basic techniques for the purpose of juxtaposing relaxation with anxiety. The first technique is progressive deep muscle relaxation training and the second is systematic desensitization of anxiety through imagination. The patient is instructed to relax and then tense up for intervals of 10–15 seconds each; the patient repeats this maneuver using various different muscle groups or parts of the body followed by breathing exercises. Then, after discussing with the patient which real-life situations arouse the phobic symptoms, the therapist incorporates each scene into an anxiety list or anxiety hierarchy; this list constitutes the basic therapeutic tool. (Each scene or situation is arranged hierarchically on the basis of level of anxiety generated in the patient, with a ranking system of 1–10.) Starting with the weakest elicitor of anxiety in the hierarchy, the therapist asks the patient to imagine the anxious circumstance for a few minutes and then instructs the patient to concentrate on relaxing; this process is repeated until the patient can imagine the scene without feeling any anxiety. The therapist ascends the anxiety list item by item in the same manner. When this process is finished, the real-life situation that has created the phobia has lost its capacity to elicit anxiety.

A more recent variation of this approach is, ironically, a direct reversal of this procedure. The therapist starts not with the bottom but with the top of the anxiety continuum; the patient is flooded with the strongest anxiety-eliciting stimulus situation of his/her imagination and keeps this in mind until the anxiety dissipates. Then, with successive repetitions of the same scene, the patient's anxiety progressively lessens until he/she is immune to anxiety in that situation. This basic technique is referred to as implosion (Stampfl's implosive therapy).

A cognitive variation of this approach is the technique of thought-stopping. In this variation the patient puts into words the anxiety-producing situations instead of merely imagining them. As the patient speaks about himself/herself in these situations the therapist suddenly interrupts the train of anxious verbalizations by shouting "Stop!" This procedure is repeated on successive occasions until the patient validates the fact that this overt suppression has indeed served to reduce the frequency of the anxiety-loaded thoughts. Ellis' rational therapy represents an elaboration of this cognitive approach on a larger and more varied scale.

The behavioral counterpart of the psychodynamic procedure of working-through is behavioral rehearsal within the confines of therapy as well as assignments to be worked on outside of therapy; these are important parts of the total behavioral treatment. For example, the patient might be directly trained in certain social skills that may first be role-played or rehearsed within the course of therapy as well as explicitly instructed, tested out in outside real-life situations, and reviewed in subsequent sessions.

A special instance of this method is assertiveness training, a technique of instruction and practice of interpersonal behaviors involving the relatively direct expression of one's positive and negative responses to others. Wolpe claimed that assertive responses consti-

tute a major class of behaviors that could be used as an alternative to relaxation responses in the function of reciprocally inhibiting anxiety. Assertive training by means of behavior rehearsal, whether or not it is used as a technique for expressly countering anxiety, has been incorporated into a variety of schools that use the methods of the behavioral laboratory.

Variations on the Behavioral Theme

Three broad types of behavior therapies or behavior modification are considered under the umbrella of the behavioral theme (74): one, based on the early classical Pavlovian paradigm, primarily uses systematic desensitization or extinction of anxiety techniques (e.g., Wolpe's reciprocal inhibition therapy); a second type, based on an operant Skinnerian paradigm, uses direct reinforcement by means of reward/punishment procedures (e.g., Allyon and Azrin's token economy); and a third type, based on a human social learning paradigm, is contingent on direct modeling or shaping procedures (e.g., Bandura's modeling therapy). The latter type of therapy extends to a variety of new systems of directive psychotherapy that expressly aim at attitudinal or philosophical restructuring, using methods of the behaviorist's laboratory. Such so-called integrity therapies, although they share the fundamental learning or problem-solving stance, are usually more actively advisory and/or exhortative in their therapeutic techniques (e.g., Ellis' rational therapy, Glasser's reality therapy, and Sahakian's philosophic psychotherapy).

Another way of viewing the scope of these behavioral variations is through the evolution of their targets of change from external to internal alterations in man's learnings. The earlier behavior therapeutic systems addressed overt behaviors and fears (e.g., Wolpe); the more recent systems are directed to more covert values and beliefs (e.g., Ellis). The most recent approaches venture into the reaches of the most inaccessible and involuntary mental and physiological states and responses, such as heart rate, blood pressure, and brain waves (e.g., biofeedback).

THE EXPERIENTIAL THEME

The Nature of Man and His Ills

In terms of therapeutic ideology, a major source of divergence and disagreement for the founders of schools of psychotherapy since Freud has been their inability to reconcile what they regard as a largely deterministic or defeatist image of man. This includes the renunciation of a dynamic conceptualization of man as a predominantly passive or instinctually regressive recipient of his conflictual drives, subservient to the less conscious aspects of himself. The experientialists criticize classical psychotherapy's overcommitment to the canons of science and its concurrent underplaying of man's ethical dimension, that is, his will, choices, and moral relation to others. Through psychotherapeutic practices and overemphasis on technique, man becomes impersonalized, compartmentalized, calculated, managed, and/or analyzed and thereby diminished instead of truly experienced by others or himself (20, 26, 53, 75).

Haigh, an experientialist, has criticized the behavioral conceptualization as follows:

> The therapeutic process [is] essentially concerned with the experiential anguish of isolation and alienation. These experiences of isolation, encapsulation, alienation derive from social programming. . . . The central problem cannot be understood exclusively at the level of overt behavior, [but] must be understood as involving incongruence between overt behavior and inner experience. Reinforcement learning theory is inadequate for translating this central problem because it doesn't include concepts representing human experience. The behavioral therapy techniques associated with reinforcement learning theory are potentially harmful because they involve the very same programming approach which induced these neurotic problems in the first place (76).

The experiential conceptualization represents an increasingly emerging exaltation of man in order to counter alienation, that is, the fostering of the fullest exploration of the unique and universal nature of man's self. It is expressly devoted to the self-transcendent quality of human experience. In Frankl's words, "Man is basically striving to find and fulfill meaning and purpose in life" (77, p. 252).

This reaching out involves a transpersonal as well as intrapersonal dimension. According to Arendsen-Hein, the intrapersonal refers to an "ego-centered level . . . where the main concern is the discovery of one's individuality, of one's emotional states and their representation in the physical body"; the transpersonal, on the other hand, is "spiritually oriented towards ultimate reality, . . . unity on the human, universal, or cosmic plane . . . in which [the person] experiences a transcendence of his ego boundaries into a universal consciousness" (78).

The experientialist tends to view man as an inherently active, striving, self-affirming, and self-potentiating entity with almost limitless capacity for positive growth, and the experiential therapies typically opt for growth and not mere healing of illness. Their therapeutic goal is attaining maximal awareness or a higher state of consciousness, in which, according to May and associates, "to be aware of one's world means at the same time to be designing it" (20, p. 60). Experientialists therefore direct themselves to such expansive dimensions as self-determination, creativity, and authenticity and make use of a potpourri of methodologies that aspire to an ultimate integration of the mind, body, and more recently, soul of fragmented man.

The experiential stance historically reflects the incorporation of the basic philosophy of the European existentialist, with his/her concern for the essential issues of man's being or becoming; the methodology of the phenomenologist, who attempts to address data as

given in order to tap their meaning and to examine patients on their own terms without recourse to preconceived theoretical formulations of a causal or diagnostic nature; and, now more than ever, the religious teachings and techniques of the Eastern mystic, who presumes to bridge the mind-body split in seeking man's spiritual center. All, according to May and associates, focus on "man's most immediate experience . . . [i.e.,] that to fully know *what* we are doing, to feel it, to experience it all through our being, is much more important than to know *why*. For they hold, if we fully know the *what*, the *why* will come along by itself" (20, p. 83).

Pathology is regarded as the reduced expression of one's potential, the result of blocking and the loss of congruence with or repressing of one's internal self-experience. Both the psychodynamic and the experiential (essentially existential) themes depict the neurotic personality as suffering from repression and fragmentation. The dynamic view postulates repression of instinctual drives, especially sexual ones, while the experiential view construes repression as an ontological phenomenon, "the loss of a sense of being, together with the truncation of awareness and the locking up of potentialities which are the manifestation of this being" (20, p. 86).

Neurosis is a fundamental universal despair resulting from the individual's estrangement from himself and his society (or world). Comparably, anxiety, in marked contrast with the behavioral equation of anxiety with specific circumscribed fears, refers to "the anxiety of man facing the limits of his existence with the fullest implications . . . death, nothingness" (20, p. 118). Such anxiety manifests itself at every moment as man stands against the reaches of his own possibilities. Moreover, the origin of guilt accrues from the forfeiting of one's potential, for which the person alone is responsible.

In Maslow's words, pathology is "human diminution" (instead of neurosis), "the loss or not-yet-actualization of human capacities and possibilities" (79, p. 124). Thus health and illness, including all of the standard psychiatric categories, reside on a continuum—the differential between what one construes himself to be versus what one can become. The overall ideal or ultimate state of health refers to man as maximally conscious and real at every moment, to wit, according to Denes-Radomisli, man as "vital, immediate, spontaneous, authentic, and active" (80, p. 104).

Therapeutic or Change Processes

The experiential schools of psychotherapy trade intellectual cognition and insight for emotion and experience, forsaking the there-and-then of the distant past for the here-and-now of the immediate present.

Experiencing is a process of feeling rather than knowing or verbalizing; occurs in the immediate present; is private and unobservable but can be directly referred to by an individual as a felt datum in his own phenomenal field; acts as a guide to conceptualization; is implicitly meaningful, although it may not become explicitly so until later; and is a preconceptual organismic process. The many implicit meanings of a moment's experiencing are regarded not as already conceptual and then repressed; rather, they are considered in the awareness but as yet undifferentiated. In total, according to Gendlin, "therapeutic change occurs as a result of a process [of experiencing] in which implicit meanings are in awareness, and are intensely felt, directly referred to, and changed, without ever being put into words" (81, p. 239).

Therapeutic change through experiencing usually occurs by means of a real or congruent interpersonal relationship between the patient and the therapist. In the latter regard, May and associates said,

> Beyond all considerations of unconscious determinism—which are true in their partial context—the only thing that will grasp the patient, and in the long run make it possible [for him/her] to change, is to experience fully and deeply that [he/she] is doing precisely this to a real person . . . in this real moment. (20, p. 83)

One variation of this thesis, especially applicable to Roger's client-centered therapy, reflects the underlying positive belief that every organism has an inborn tendency to develop its optimal capacities as long as it is placed in an optimal environment. Thus, according to Hoehn-Saric, the patient is offered "an optimistic self-image; he understands that he is basically good and full of potentials. . . . Therefore, the therapist does not need to challenge or shape the patient, he has only to provide the warm and understanding milieu which will enable the patient to unfold his latent potentials" (82, p. 261).

Unlike transference, which is dependent on the revival of a former interpersonal relationship, experiential encounter works "through the very fact of its novelty." Through encounter the therapist serves as a catalyst in whose presence the patient comes to realize his own latent and best abilities for shaping his own self (20).

The Nature of the Therapeutic Relationship

Although methods may vary, the real here-and-now therapeutic dialogue or mutual encounter between therapist and patient is the sine qua non of many of the experiential schools. It is, according to Ford and Urban, "an emotionally-arousing human relationship in which each person tries to communicate honestly with the other both verbally and nonverbally" (26, p. 470).

Rogers described the flavor of the therapeutic encounter as follows:

> I let myself go into the immediacy of the relationship where it is my total organism which takes over and is sensitive to the relationship, not simply my consciousness. I am not consciously responding in a planful or analytic way, but simply in an unreflective way to the other individual, my reaction being based (but not consciously) on

> my total organismic sensitivity to this other person. I live the relationship on this basis. (83, pp. 267–268)

These approaches to psychotherapy ideologically aspire to an egalitarian treatment model. The human alliance is not of physician to patient or teacher to student but of human being to human being. May and associates presented the following rationale: "The therapist is assumedly an expert; but, if he is not first of all a human being, his expertness will be irrelevant and quite possibly harmful" (20, p. 82). Rogers stated that if the patient is viewed as an object the patient will tend to become an object (83). Therefore, the therapist says, "I enter the relationship not as a scientist, not as a physician who can accurately diagnose and cure, but as a person, entering into a personal relationship" (83, p. 267). Naturally, what one construes to fall within the domain of personal or real in a therapeutic relationship is open to interpretation.

In sum, although Seguin pointed out that the quality of the healer-patient relationship (and the form of therapeutic love or eros that is transmitted) is "different from the one between father and son, teacher and pupil, friends, and, of course, lovers" (84), the experiential theme rejects the paradigm of the parent-child relationship of the dynamic theme and the teacher-student paradigm of the behavioral theme and opts for something closer to the latter conceptualization (i.e., friends and lovers) in its paradigm of the therapeutic relationship.

Techniques and Methods

There is an assortment of schools of psychotherapy within the experiential theme that recoils at the idea of therapeutic technology. These schools, which are predominantly existential, renounce technique as part of their philosophy of understanding human existence. They feel that the chief block in the understanding of man in Western cultures has been an overemphasis on technique and a concomitant tendency to believe that understanding is a function of or related to technique. Rather, according to May and associates, they feel that "what distinguishes [forms of] existential therapy is not what the therapist would specifically do, . . . but rather the *context* of his therapy" (20, p. 77). That is, according to Chessick, it is "not so much what the therapist says [or does] as what he *is*" (53, p. 243). Indeed, in this regard the existential schools of psychotherapy have been criticized for their vagueness regarding technical matters in the conduct of psychotherapy. Ford and Urban's analysis of their approach concluded that "they have developed a new way of thinking about patients, but it does not lead them to *do* anything different in treatment" (26, p. 469).

Less harshly, the experiential schools aspire to flexibility or innovation in their actual methods as long as these methods are useful in the therapist's attempt to experience and share as far as possible the being of the patient. Here the aim or rationale of all techniques would be to enter the phenomenological world of the patient. In direct contrast to the view of the dynamic therapist, the experiential therapist does not concern himself/herself with the patient's past, the matter of diagnosis, the aspiration of insight, the issue of interpretation, or the subtle vicissitudes of transference and countertransference. Unlike the behavioral therapist, the experiential therapist expressly does not set goals for the patient and does not direct, confront, or otherwise impose his/her personality on the patient with directives in the form of behavioral instructions or problem-solving preferences. Techniques that involve placing the therapist's judgments or values above those of the patient are considered anathema to the requirements of unconditional acceptance of the patient and placing the locus of control within the patient. It may also be noted here that Rogerian methods as well as others within the more classically existential framework retain a methodological framework of essentially verbal interchange between therapist and patient.

Although they share the same basic faith in the therapeutic encounter and the emphasis on feelings, other schools under the experiential umbrella are often antiverbal in approach. Such schools (e.g., Gestalt therapy), view overintellectualization as part of the patient's problem, i.e., a manifestation of defense against experiencing or feeling, and discourage it as part of the therapeutic endeavor. These therapies attempt to accentuate activity over reflection, emphasize doing rather than saying, or, at the minimum, aim to combine action with introspection. The goal of experiencing oneself includes developing the patient's awareness of bodily sensations, postures, tensions, and movements, with an emphasis on somatic processes. Awareness of oneself as manifested in one's body can be a highly mobilizing influence. The main thrust of therapy is therefore to actively arouse, agitate, or excite the patient's experience of himself/herself, not simply let it happen.

Among the techniques for expressing one's self-experience in such schools is the combination of direct confrontation with dramatization, i.e., role-playing and the living out of fantasy in the therapeutic situation. This means that under the direction (and often the creation) of the therapist the patient is encouraged to play out parts of himself/herself, including physical parts, by inventing dialogues between them. Performing fantasies and dreams is typical and considered preferable to their mere verbal expression, interpretation, and cognitive comprehension. In variations of the somatic stance, body and sensory awareness may be fostered through methods of direct release of physical tension and even manipulations of the body to expel and/or intensify feeling.

In yet other attempts to unify mind, body, and more especially, spirit, the immediate experience of oneself by focusing on one's spiritual dimension is sought. This is most often accomplished through the primary technique of meditation. The ultimate state of profound rest serves to transcend the world of the indi-

vidual ego in that it is a higher reality or state of consciousness that the individual ego subserves. Major methods of will training and attention focused on a special word-sound or mantra, for example, serve to create an egoless or nonegocentered transcendent state.

Variations of the Experiential Theme

The therapeutic systems that have evolved under the experiential theme represent various approaches, each propelled by the immediate moment and geared toward the ultimate unity of man. These include the following: 1) a philosophic type, which reflects existential tenets as a basis for the conduct of psychotherapy and pivots on the here-and-now mutual dialogue or encounter while retaining essentially verbal techniques (e.g., Roger's client-centered therapy and Frankl's logotherapy); 2) a somatic type, which reflects a subscription of nonverbal methods and aspiration to an integration of self by means of focusing attention on subjective body stimuli and sensory responses (e.g., Perls's Gestalt therapy) and/or physical-motor modes of intense abreaction and emotional flooding in which the emphasis is on the bodily arousal and release of feeling (e.g., Lowen's bioenergetic analyses and Janov's primal scream therapy); and, finally, 3) a spiritual type, which emphasizes the final affirmation of self as a transcendental or transpersonal experience, extending man's experience of himself to higher cosmic levels of consciousness that ultimately aim to unify him with the universe. This is primarily accomplished by means of the renunciation of the individual ego in the establishment of an egoless state by meditation (i.e., relaxation plus focused attention), in which one reaches a state of profound rest (e.g., Transcendental Meditation), a spiritual synthesis that may be amplified by various techniques of self-discipline and will-training and practice of disidentification (e.g., Assagioli's psychosynthesis).

CONCLUSIONS

Individual names given to different schools of psychotherapy often attempt to capture, if not exalt, their uniqueness; at the same time, the very names may serve to mask their derivations and the similarities they share with other systems. The schema presented here subsumes a large array of therapeutic schools that have proliferated under three broad themes since Freud. Each major theme as depicted here in its prototypic or pure form has a unity of its own; each dimension is broadly congruent with the others in its domain and is overtly antithetical to those dimensions described in the other two themes. However, in reality these are rarely categorical distinctions. Therapeutic boundaries in actual practice can and do overlap.

The systematic approach presented in this paper allows us to consider the dimensions of greatest departure as well as convergence in the ever-expanding field of the psychotherapies. In so doing, it is hoped that psychotherapeutic schools and their therapeutic processes will be more closely and critically explored.

Psychotherapy of Severe Depression

BY SILVANO ARIETI, M.D.

The author discusses his clinical experiences in treating severely depressed patients with psychotherapy. The psychotically depressed person cannot use normal mechanisms to recuperate from sadness because he is prevented from doing so by a preexisting life ideology that may include living for a dominant other or a dominant goal and that restricts his vision of alternative approaches to living. The therapist treating the severely depressed must initially assume a strong role; later, he helps the patient recognize depressive cognitive patterns and guides and motivates him to try other ways of living.

PSYCHOTHERAPY of affective psychoses is still in the pioneer stage. Although depression has been treated with psychotherapy for a long time, generally the cases treated had not reached the psychotic level. It is true that, unlike schizophrenia, psychotic depression was treated psychoanalytically relatively early in the history of psychoanalysis (1, 2). However, these cases have been very few and as a rule the patients were treated in the intervals between the attacks of depression.

According to my clinical experiences, the intensity of the depression should not deter the therapist from making psychotherapeutic attempts (3). Psychotherapy becomes a necessity when drug therapy and shock therapy have been ineffective, when the syndrome recurs in spite of these treatments, or when the patient refuses to try physical therapies again. Contrary to common belief, most cases of psychotic depression do respond to psychotherapy if a proper therapeutic procedure is adopted.

The procedure I am going to describe was applied to 12 cases of extremely severe depression treated on an ambulatory basis. A much more extensive report of these cases will appear elsewhere (4). The patients were 9 women and 3 men; 10 of them had suicidal ideation. The patients were treated for at least 18 months with a minimum of 2 sessions a week. After at least 3 years from termination of treatment I can now report that full recovery with no relapses was obtained in 7 patients, marked improvement in 4, and failure in 1.

It may be useful before proceeding to compare the psychotherapist's tasks in treating a case of psychotic depression and a case of schizophrenia. Both the schizophrenic and the very depressed patient lament what they have come to know and feel about life. In both conditions there is a close interweaving of a drama of the present with a drama of the past. In both conditions the therapist must understand each of the two dramas. The schizophrenic rejects and symbolically destroys the world, which he perceives as hostile, and attempts through projection and special cognition to rebuild his own private universe. Thus his failure and his concern tend to become of cosmic magnitude. The person who is depressed to a psychotic degree does not reject the world, and acts to a certain extent like a mother who does not reject a bad child. The psychotically depressed patient does not even reject his suffering, but accepts it, all of it, and the suffering expands more and more, into a psyche that seems endless in its capacity to experience sorrow.

Dr. Arieti is Clinical Professor of Psychiatry, New York Medical College, New York, N.Y. Address reprint requests to him at 125 East 84th St., New York, N.Y. 10028.

PSYCHODYNAMIC VIEW OF PSYCHOTIC DEPRESSION

Normal Sadness

The patient cannot put into operation the mechanisms adopted by a normal person who recuperates from a feeling of sadness, grief, or bereavement (5). For example, a normal individual hears the news of the unexpected death of a person he loved. After he has understood and almost instantaneously evaluated what that death means to him, he experiences shock, then sadness. For a few days all thoughts connected with the deceased person will bring about a painful, almost unbearable feeling. Any group of thoughts even remotely connected with the dead person will elicit sadness. The individual cannot adjust to the idea that the loved person does not live any more. And, since that person was so important to him, many of his thoughts or actions will be directly or indirectly connected with the dead person and will therefore elicit sad reactions.

Nevertheless, after a certain period of time, that individual adjusts to the idea that the person is dead. By being unpleasant, sadness seems to have a function—its own elimination. It will be removed only if the individual is forced to reorganize his thinking and to search for new ideas so that he can rearrange his life. He must rearrange especially those ideas that are connected with the departed, so that the departed will no longer be considered indispensable—indispensable,

that is, to the equilibrium of the psychological structure of the survivor. Like pain, sadness stimulates a change in order to be removed, but it is a psychological change, an ideational change, a rearrangement of thoughts and clusters of thoughts. Eventually actions will also be altered as a consequence of this cognitive rearrangement. Bowlby (6–8) has described the active search in children deprived of their mother, and Parkes (9) has reported the various ways in which widows search to repair their losses. In other words, in normal sadness, after a period of slowness or inactivity that prevents quick responses there is a reorganization of functions, first cognitive and then motor, which aims at bringing about a return to a state of normality.

The person who is psychotically depressed cannot use these recuperative mechanisms. He finds himself in a psychological trap from which he cannot escape. The overpowering feeling of depression keeps in a state of unconsciousness or dim consciousness cognitive structures and patterns of life that started at an early age. In other words, depression has, among other functions, that of repressing cognitive structures.

Ideology of Psychotically Depressed Patients

My studies of patients treated with psychotherapy indicate that there is always a preceding ideology, a way of seeing oneself in life in general, in relation with another particular person, or in relation to a goal to be achieved that prepares the ground for the depression. Although depressive affect prompts the person to search for and find pessimistic ideas that justify the affect, the opposite initially occurs. The patient's ideology preexisted and was kept alive for a long time in conscious or unconscious forms. Although the patient might have been aware of the importance of these systems of cognitive constructs, he was not conscious of their origin, of how much they involved, or of all the ramifications, assumptions, presuppositions, and feelings connected with them. These cognitive domains in most cases originated in childhood and continued to accrue throughout life.

In many cases these cognitive structures and patterns made the patient live not for himself but for another person, whom I have called the dominant other. The dominant other is represented most often by the spouse, less frequently by the mother, a lover, an adult child, a sister, the father. The dominant other may be represented through anthropomorphization by the firm where the patient works, a social institution, or class of people. Some other patients live for an inaccessible aim, which I have called the dominant goal.

When the patient realizes the failure of his pattern of living, he also recognizes that he is unable to change it. Thus he finds himself in a state of helplessness and hopelessness. A frequent example is that of a woman who used to consider her husband a dispenser of love and affection, a protector, a friend, a partner in every respect. She then starts to see him as an authoritarian person who imposed his rule, at times in a subtle, hardly visible way, at other times in a manifest manner. The patient's own life, at first believed devoted to love and affection, is seen now as not genuine. The patient has been excessively compliant, submissive, and accommodating. By doing always what the husband wanted and denying her wishes, she has not been true to herself; as a matter of fact, she feels she has betrayed herself. The patient may exaggerate and see the authoritarian husband as a real tyrant, somebody who deserves not love, but hate, somebody who enslaved her and changed her real nature. In most cases she does not realize that she also played a role in establishing this type of interpersonal relation. By following a pattern of submissiveness that started early in life she developed ingratiating attitudes and was willing to accept fully a patriarchal type of society and family and to keep the dominant other, in the belief that she was perfectly contented or even happy in her way of living.

The emerging new ideas about the husband, however, cannot be accepted. A woman who had not followed the pattern of submission and dedication at any cost would now try new ways for what remains of her life (e.g., separation, divorce, new affections), but the patient cannot do this. She cannot conclude that she has wasted so much of her life. She still needs the same dominant other to praise her and to approve of her to make her feel worthwhile. How could he continue in that capacity if she expresses hate, rebellion, or, in some cases, even self-assertion? The patient has reached a critical point at which a realignment of psychodynamic forces and a new pattern of interpersonal relationships are due, but she is not able to muster them. This is her predicament. She is helpless. She either cannot visualize alternative cognitive structures that lead to recuperative steps or, if she is able to visualize them, they appear unsurmountable. At other times these alternatives do not seem unrealizable, but worthless, since she has learned to invest all her interest and desires only in the relationship that failed.

Depression following realization of failure to reach the dominant goal is more common among men. The patient realizes that he is not going to be a great doctor, lawyer, politician, writer, actor, industrialist, lover, or musician, but he cannot change the direction of his goal. If the goal is not achieved, life is worthless. If he wanted to be a great conductor, a Toscanini, now he has to face the fact that he is not a Toscanini, that he is himself, John Doe. But he has no respect for John Doe, as he should. He believes John Doe is nothing. There is some tangential and partial justification in the patient's assessing himself in this negative way because he spent so much of his thoughts in being Toscanini, and his psychological life without this overpowering fantasy seems empty. The limitations of the patient, determined by his rigidity and adherence to an inflexible pattern of life, do not provide him with alternatives. As in the patient who experienced failure in the relation with the dominant other, the patient may visualize alternatives but they seem either unsurmountable or worthless.

If space permitted, I would also touch on the inability to find alternative cognitive structures in patients who become depressed after loss of spouses, parents, positions, hopes, etc. The post-partum depression occurring in the woman who cannot accept the new pattern of life required by motherhood is another very complex situation (10).

In these cases sadness cannot be removed and is transformed into deep depression. When unpleasant ideas occur they are submerged by the wave of depression. The cognitive basis of the condition is repressed, but the painful feeling is very intensely experienced at the level of consciousness. This last remark may seem at variance with what we observe in many patients who express depressive ideas about the way they view themselves, the world, and the future. Beck (11–13) has carefully described the cognitive elements that keep the patient in a state of depression. In my experience with cases of severe depression, these depressive thoughts are used by the patient to justify his preexisting depression. They replace much more basic and more intense depressive trends, which have to be studied longitudinally, since they go back to the early life of the individual (5).

THERAPEUTIC PROCEDURE

Initial Tasks of the Therapist

The first task of the therapist is not that of interpreting to the patient the inappropriateness of his patterns of living or the maladaptive quality of his endless sorrow but that of entering into his life with a strong and significant impact.

The therapist assumes an active role. He is a firm person who makes clear and sure statements. He is compassionate, but not in a way that can be interpreted as acknowledgment of helplessness. He tells the patient that he knows how deep his anguish can be, but that he also knows that depression does not come from nothing. There is always a reason, which the patient, alone, cannot find. In other words, the patient is invited to lean on the therapist.

When the therapist succeeds in establishing rapport and proves his genuine desire to help, to reach, to nourish, to offer more clarity about certain issues and hope about others, he will often be accepted by the patient, but only as a dominant third, i.e., a third person in addition to the patient and the dominant other. Immediate relief may be obtained because the patient sees in the therapist a new and reliable love object. Although the establishment of this type of relatedness may be helpful to subsequent therapy, it does not constitute a real cure; as a matter of fact, it may be followed by another attack of depression if the patient realizes the quality and limitation of this relation. The therapeutic approach must proceed toward a more advanced stage, in which the therapist is no longer a dominant third, but a significant third—a third person who, with his firm, sincere, and unambiguous type of personality, wants to help the patient without making threatening demands or requesting a continuation of the patient's pathogenetic pattern of living. Whereas the dominant other is rigid and static, the significant third will change rapidly and will eventually appear as a person who shares life experiences without aiming at domination.

The point must be stressed, however, that in the initial stage of the psychotherapy of severe depression, like in the psychotherapy of schizophrenia, the therapy must somewhat conform to the patient's pathology and, often, in less pronounced forms, even repeat it. Otherwise treatment is immediately experienced by the patient as dangerous and is rejected before a meaningful therapeutic relatedness has been established.

Once the therapist has been able to gather enough information, the relation with the dominant other must be interpreted. The patient must come to the conscious realization that he did not know how to live for himself. He never listened to himself; in situations of great affective significance he was never able to assert himself. He cared only about obtaining the approval, affection, love, admiration, or care of the dominant other. As Bemporad (14) described, the patient was incapable of autonomous gratification; he had to obtain it from the dominant other.

Potential Problems

When the therapist succeeds in making some headway in understanding the patient's psyche, several developments that must be promptly coped with may occur. The patient may become less depressed but angry, either at the dominant other or the therapist, whom he would like to transform into a dominant third. The anger and hostility toward the dominant other (most frequently the spouse) is at times out of proportion. Once the ideations which were repressed or kept at the periphery of consciousness come to the surface, the dominant other may be seen as a tyrant, a domineering person who has subjugated the patient. The therapist may have a difficult task in clarifying the issues. At times the dominant other has really been overdemanding and authoritarian and has taken advantage of the placating, compliant qualities of the patient. Often, however, it is the patient himself who, by being unable to assert himself and by complying excessively, has allowed certain patterns of life to develop and persist. Now, when he wants to change these patterns, he attributes the responsibility for them to the dominant other. No real recovery is possible unless the patient understands the role that he himself has played in creating the climate and pattern of submissiveness. Similarly, if the major pathogenetic constellation of his psyche is his concern with the dominant goal, he must understand why he gave such supremacy to the achievement of that goal. Did he see in such a goal the only possible meaning of his life, and why?

Helping the Patient Perceive New Ways of Living

The therapist must not only help the patient bring to full consciousness cognitive patterns and their effect on his life; he must also gradually guide the patient to visualize different patterns and to invest them with hope and desires. The patient who has understood the role he has played in the dynamics of his condition will lose a sense of passivity and will feel less helpless and less inclined to accept a feeling of hopelessness. He will learn to assert himself and to aim at what is really meaningful to him and gratifying.

Bemporad and I have elsewhere (4) described the varieties and details of the complicated psychotherapeutic approach to the severely depressed. However, even in a short presentation like the present one, a few more important issues cannot be omitted.

In a considerable number of patients, although a smaller number than used to be, the depression is accompanied by a profound guilt feeling. The patient feels responsible for whatever has happened that brought about his psychological collapse. If some energy is left, it must be used for self-punishment. He feels vaguely that enough punishment will restore a self-image acceptable to him. The guilt is often actually based on hate for the dominant other, in a way reminiscent of the sadistic trends of the depressed that Freud (2) described as directed against the incorporated love object. The guilt feeling has repeatedly helped the patient to choose a pattern of atonement and submission to the dominant other in order to placate him and to obtain his love and approval. If such approval is not obtained, the patient's guilt feeling increases because in his cognitive structure lack of approval means not having done enough to deserve it. Moreover, in accordance with his patterns of living he has learned to transform anxiety into guilt. As painful as the guilt feeling is, the patient is aware that the possibility of suffering, atoning, and placating is within his capabilities, whereas with anxiety he is at a loss; he does not know what to do about it. It is important to explain these mechanisms to the patient. However, the greatest relief from guilt feeling will occur when he has transformed his relation with the dominant other.

When the patient has somewhat improved and is able either by himself or with the help of the therapist to realize that alternative ways of living are available to him, he may state that he is afraid to embark upon them, even though the depression has lifted and the motor retardation is no longer present. The patient may be afraid of attempting new ways of living because they are unknown and unfamiliar. Other inhibiting factors stem from the fact that these new ways seem extremely remote and do not arouse in him motivation toward their achievement. The patient, who has been for so long entrenched in his complexes and enduring patterns of living, has never day-dreamed about or invested feelings in these alternatives. Again the therapist must help the patient gradually to develop the lacking motivation for different paths of living.

The patient who has partially recovered continues, nevertheless, to feel more at home with the feeling of depression than with other moods. He may exploit any negative event or thought to become depressed again. We must repeatedly show him how he uses every minor unpleasant event or thought to justify his depression, which initially stemmed from a deeper source.

At other times the patient entertains ideas half-way between these superficial depressive ideas that he exploits and ideas that are genuinely related to the deep problems of which he has now acquired awareness. He may brood over what he did not have or may have a feeling of self-betrayal. He has some realization that some aspirations have to be given up; he has the feeling that he cannot count on the recurrence of opportunities that he did not grasp, and so on. The therapist must guide the patient so that he can catch himself in the act of having these ideas or in an attitude in which he expects to be or to become depressed. If he becomes aware of these ideas and of expecting to be consequently depressed, he may be able to intercept the process and to avert the depression. He will become more and more receptive to alternative ways of living.

As a final point, I wish to mention that psychotherapy as described in this paper does not exclude concurrent drug treatment with antidepressants such as MAO inhibitors or tricyclics. I have resorted to such combined treatment with satisfactory results. I want to stress again, however, that psychotherapy alone can be an effective treatment in severe depression and that it may have to be used to the exclusion of other types of treatment in the conditions which I mentioned at the beginning of this paper.

The Isaac Ray Award

The American Psychiatric Association invites nominations for the Isaac Ray Award for 1978. This award, in memory of Margaret Sutermeister, is presented to a person (psychiatrist, attorney, or someone from a discipline related to human behavior) who has made outstanding contributions to forensic psychiatry or to the psychiatric aspects of jurisprudence. The purpose of this award is to promote better understanding between the law and psychiatry. The award, which will be presented at the Convocation of Fellows at the annual meeting of the American Psychiatric Association in Atlanta, Georgia, in May of 1978, includes an honorarium of $2,000. The recipient agrees to present his or her work at an institution of higher learning (or other suitable location) and to present the manuscript for publication. The presentation will be located and timed to give maximum exposure to students and practitioners of law and medicine and to other professionals.

Nominations are requested by the deadline of September 12, 1977, from any interested professional, and may be submitted to: Naomi Goldstein, M.D., Chairperson, Isaac Ray Award Board, 15 West 81st St., New York, N.Y. 10024.

Continuing Education, Recertification, and Examination Anxiety

BY EUGENE B. FEIGELSON, M.D., AND WILLIAM FROSCH, M.D.

A substantial majority of the 645 psychiatrists responding to a questionnaire survey favored mandatory continuing education and evidence of continuing education as a requirement for relicensure. The respondents' overwhelming repudiation of recertification may be based on examination anxiety. The respondents recognized the value of continuing education, were even willing to document it in order to be relicensed, but did not wish to be examined. Those respondents who were younger, Board-certified, and had an academic appointment were more likely to favor continuing education requirements in order to be relicensed. Private practitioners were underrepresented among the respondents, highlighting the important role that APA and its district branches must play in developing meaningful continuing education opportunities for psychiatrists.

CONTINUING MEDICAL education following postgraduate training has been of concern to medical educators for many years. It has become a subject of increasing importance in the past few years. The number of courses registered by the American Medical Association increased from 1,105 in 1961 to 4,862 in 1976 (1, p. 589); similarly, the number of continuing education opportunities for psychiatrists has been on the increase (1). In spite of the increasing concern about continuing education and recertification in psychiatry, little is known about the practicing psychiatrist's attitudes regarding these matters. This is at least in part the result of a paucity of studies in the area. A computer search of the literature of the last 5 years using such code words as "continuing education," and "recertification" yielded just over 100 papers. However, 50 of these dealt with the education of nonpsychiatrists, 25 with residency training, and 10 presented pious platitudes but no data. There were 7 papers on peer review and only 9 substantive contributions to the continuing education of psychiatrists. We undertook this study in an effort to provide the public deliberative process with information concerning the perceived needs and desires of the psychiatric community.

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Feigelson is Clinical Professor of Psychiatry, Columbia University College of Physicians and Surgeons, and Director of Psychiatry, St. Luke's Hospital Center, Amsterdam Avenue at 114th Street, New York, N.Y. 10025. Dr. Frosch is Professor of Psychiatry and Vice-Chairman, Department of Psychiatry, Cornell University Medical College, New York, N.Y.

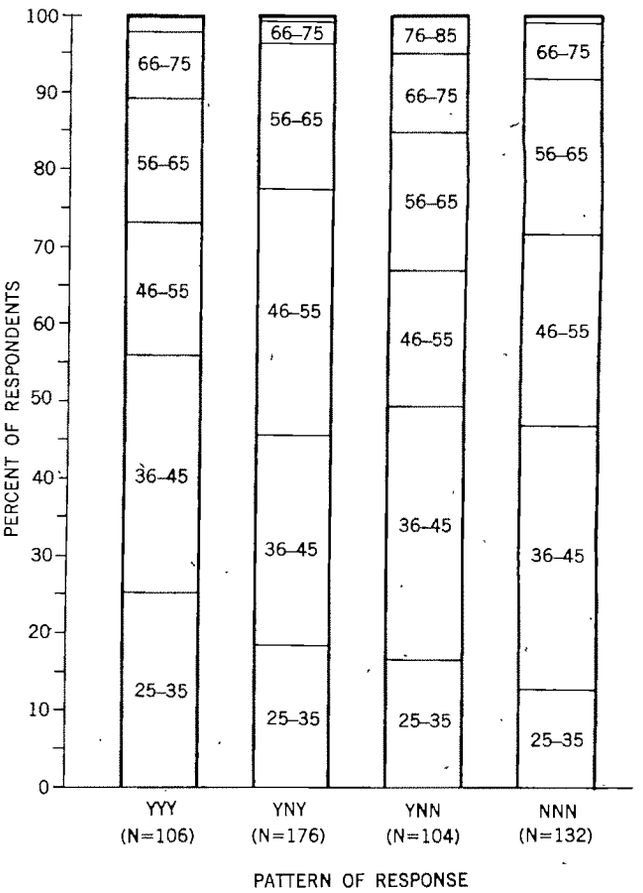
The authors wish to thank Andrea Scripture and Emily Frosch for their assistance in this study.

METHOD

We used a questionnaire designed to elicit the attitudes of different segments of the psychiatric community toward continuing education, recertification, relicensure, and curriculum.[1] The questionnaire was a modification of a questionnaire used by Naftulin and associates (2). The two-page questionnaire was mailed to the 1,500 members of the New York County District Branch of the American Psychiatric Association (APA). A total of 645 members (43%) responded to the single mailing with completed questionnaires. Demographic data and professional activity were correlated with the following key questions:

1. Should continuing education in psychiatry be required?
2. Should recertification in psychiatry be required?
3. Should evidence of continuing education be necessary for relicensure?
4. Should the APA Office of Education and the district branches become the accrediting agencies of continuing education courses?

An overall count was taken on each item in the questionnaire and then the respondents were separated into 4 groups representing the most common patterns of response to questions 1, 2, and 3 (i.e., yes, yes, yes; yes, no, yes; yes, no, no; and no, no, no). Analysis of the data revealed significant relationships between attitudes toward continuing education, recertification, and relicensure and age, Board status, and academic affiliation.



We compared the respondents with a representative sample of the New York County District Branch (N=400) by age, year of graduation from medical school, Board status, principal professional activity, academic appointment, and whether American or foreign medical graduate. The representative sample was obtained by selecting every fourth name from an alphabetical list of the district branch members and then obtaining the above information from the *Biographical Directory of the American Psychiatric Association*.

[1]The questionnaire is available from the authors on request.

TABLE 1
Comparison of the New York County District Branch Sample and the Questionnaire Respondents, in Percents.

Item	District Branch Sample (N=400)	Questionnaire Respondents (N=645)
Age		
25–35	9	17
36–45	31	29
46–55	22	25
56–65	21	19
66–75	13	8
76–85	4	2
Year graduated from medical school		
1900–1909	2	0
1910–1919	1	1
1920–1929	8	6
1930–1939	19	16
1940–1949	19	24
1950–1959	24	9

FIGURE 1
Relationship Between Pattern of Response and Age

Statistical significance was determined by complex chi-square test and contingency coefficient.

RESULTS

Table 1 presents the findings from the comparison of the 2 groups. While there was no important difference in age between the sample group and the respondents, a lower percentage of the sample had graduated from medical school after 1959 (29% versus 43%). More of the respondents were Board-certified (67% versus 58%), had an academic appointment (70% versus 53%), and were principally involved in institutional and/or academic work (43% versus 20%) rather than private practice. American and foreign medical graduates were about equally represented in both groups. Perhaps the most important finding is that full- and part-time private practitioners, who constituted the largest subgroup of questionnaire respondents (80%), were the slowest to respond to the survey.

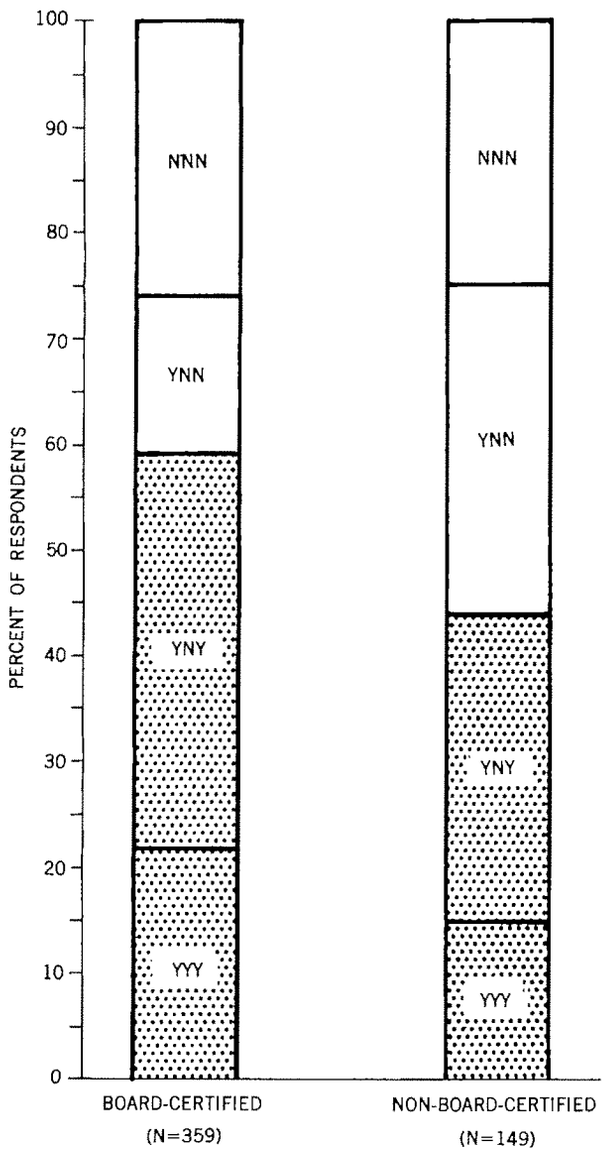
Regarding the overall response to the 4 key questions mentioned before, the respondents strongly favored mandatory continuing education in psychiatry (434 versus 151)[2] and roundly repudiated mandatory recertification (475 versus 135). A surprising majority (325 versus 272) favored evidence of continuing education as a requirement for relicensure. Most of the respondents (531 versus 71) felt that the APA Office of Education and the district branches should become the accrediting agencies of continuing education courses.

Having determined some general characteristics of the respondents, we attempted to demonstrate the relationship between the attitudes revealed by answers to questions 1, 2, and 3 and those factors shown by statistical tests to be significant.

Figure 1 employs response patterns as the basis on which to compare age groups. The overall relationship between these two is statistically significant ($p<.025$). Most readily apparent is the proportion of the YYY group aged 25–35. This proportion decreases as negativity of response increases. A second set of statistical analyses between each age group and the responses revealed a trend that is interesting in terms of the relationship between aging and negativity of response.

[2]The numbers given here and in other parts of the paper add up to less than the total sample because not all respondents replied to each question.

FIGURE 2
Relationship Between Board Certification and Pattern of Response



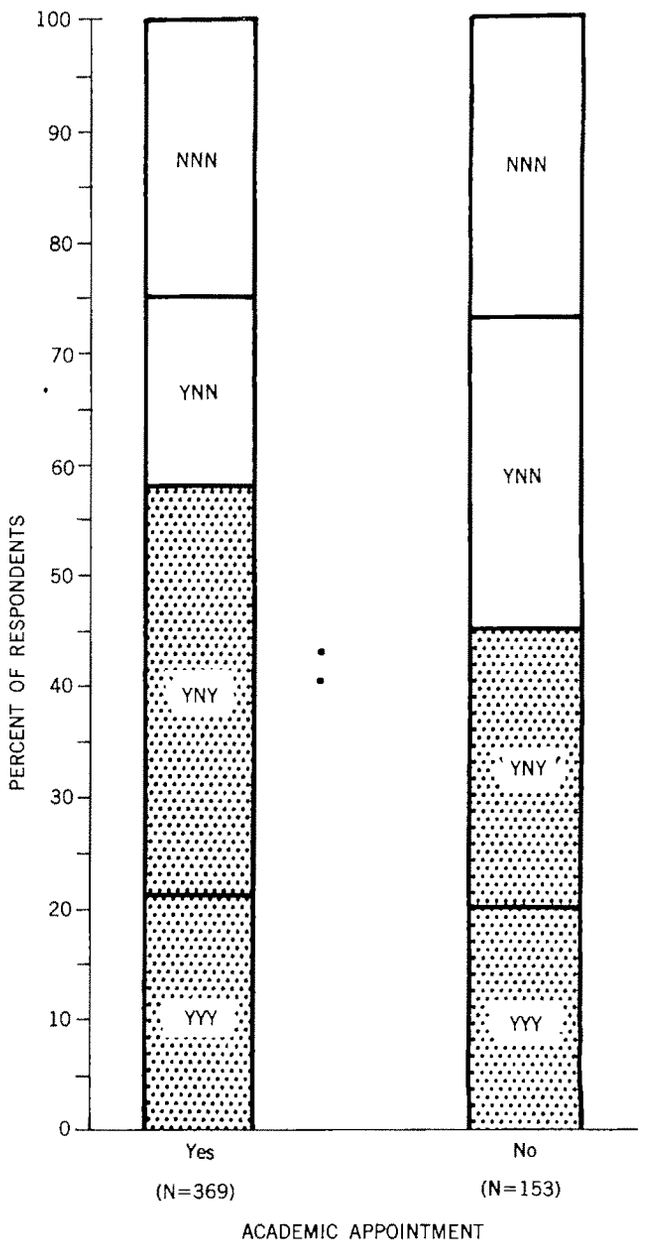


FIGURE 3
Relationship Between Academic Appointment and Pattern of Response

The results were as follows: 25–35, $p<.10$; 35–45, $p<.25$; 46–55, $p<.50$; and 56–65, $p<.90$.

Figure 2 compares the response patterns of Board-certified and non-Board-certified psychiatrists. The distinction between the two is best illustrated in the response to question 3 regarding the requirement of continuing education for relicensure. When the YYY groups are combined with the YNY groups, the result is to isolate question 3. Fifty-nine percent of the Board-certified respondents answered "yes" to question 3, compared with only 44% of the non-Board-certified respondents ($p<.005$). It is interesting to note that equal proportions of Board-certified and non-Board-certified psychiatrists fell into the NNN response group. One might speculate that those inclined to say "no" to all three questions did so out of a consistent philosophical stance.

The findings concerning the relationship between academic appointment and response pattern were similar to those regarding Board status. Figure 3 is nearly identical to figure 2; 58% of those with academic appointments answered "yes" to question 3, compared with only 45% of those without an academic appointment ($p<.01$). About equal proportions of academically affiliated and non-academically affiliated psychiatrists fell into the NNN response group.

Figure 4 illustrates the relationship between professional activity and response pattern. While there were no significant findings, it is important to remember that the respondent group was not fully representative of the district branch membership. As can be seen in

FIGURE 4
Relationship Between Pattern of Response and Professional Activity

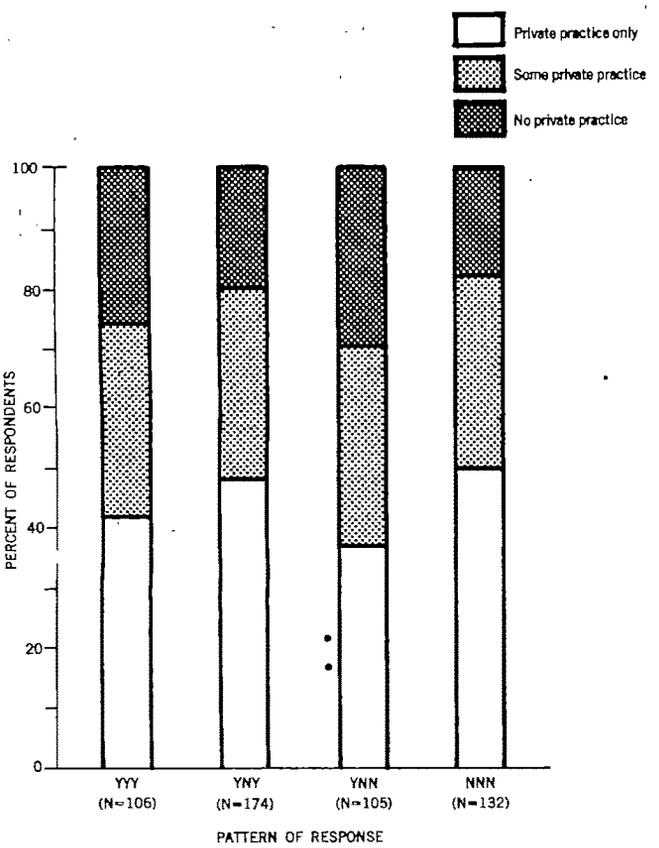

table 1, private practitioners were underrepresented among the respondents.

DISCUSSION

The test of the value of continuing education in psychiatry will be its effect on the quality of care, a difficult measurement. What is not difficult to measure is that a significant proportion of the outpatient psychiatric care in this country is provided by private practitioners, who, as a group, are probably the least responsive to the need for organized continuing medical education. Private practitioners comprised 80% of the membership of the New York County District Branch but only 57% of the respondents; conversely, institutional and academic psychiatrists comprised only 20% of the district branch membership but 43% of the respondents. Naftulin and associates (2) also reported the relative lack of interest and involvement of private practitioners in continuing medical education. Such lack of interest is surprising when one considers that academic and institutional psychiatrists work in atmospheres where utilization review and quality control are a fact of professional life; to the physician in private practice they loom as noxious threats on the horizon. Logic would suggest a larger response from the most threatened group, but this was not the case; one can only surmise that a combination of denial, avoidance, and professional style limited the response of the private practitioner.

Among the respondents the most noteworthy findings were that a substantial majority favored mandatory continuing education and even favored evidence of continuing education as a requirement for relicensure. The overwhelming repudiation of recertification suggests examination anxiety as its basis. As a group, the respondents paid high tribute to the value of continuing education, were willing to document it in order to be relicensed, but did not wish to be examined. That only 47.1% of the 22,205 members of the APA were Board-certified in 1976, in contrast to much higher percentages for other specialties, may be further evidence of examination anxiety (3). However, many psychiatrists in private practice question the relationship between continuing education programs, as well as certification, and the services they render patients; this argument may have merit but it may also be a rationalization for examination anxiety. Only 2% of the 1,062 psychiatrists responding to a survey in 1973 reported that they had ever been called upon to engage in a professional activity for which they felt ill-prepared (4).

Our attempt to correlate age, Board status, and academic affiliation with response revealed that younger members were more likely to support continuing medical education and recertification requirements; 25% of the YYY response group were 25–35 years of age; this same age group comprised only 13% of the NNN response group. Psychiatrists who were Board-certified or who had an academic appointment were more likely to favor documentation of continuing medical education activity as a requirement for relicensure.

As noted earlier, academic and institutional psychiatrists not only show more interest in continuing medical education and recertification (as indicated by their disproportionately high response rate to the questionnaire), they also are more likely to have educational experiences and quality control built into their work environment. Because the private practitioner seems relatively less interested, we feel that the organizational effort toward continuing medical education in psychiatry should have as its dominant thrust meeting the resistances and needs of private practitioners. As a group they do not tend to have substantive academic environments that provide ready access to educational experiences. In addition, there is evidence that this gap is not filled by more intensive use of journal and monograph material. Private practitioners read less than psychiatrists in academia, who in turn read less than psychiatrists in both academia and research (5). The report on recertification by the Group for the Advancement of Psychiatry discusses some of the resistances of psychiatrists to continuing medical education and recertification (6).

The findings of this study, as well as those of some of the other studies cited, suggest that for a variety of reasons the psychiatrist in private practice constitutes

the greatest reservoir or resistance to meeting any requirements, whether they be in continuing education or recertification, practice audit, or clinical competence exams. This places a greater burden on the APA district branches to develop solutions concerning continuing medical education, since they are the principal professional link between the private practitioner and the profession. Our study further suggests that an overwhelming majority of respondents were willing to vest responsibility for continuing medical education in the APA and the district branches. We must translate this vote of confidence into meaningful educational opportunities for the private practitioner. Almost every psychiatrist's fantasy includes his personal responsibility to stay abreast of his field. Some do it on their own; most do not.

The pathologist is the natural monitor of the surgeon; psychiatrists have only their conscience as their monitor. The APA, through the district branches, must assume this responsibility. In so doing, study and attention must be given to how psychiatrists learn. For example, continuing discussion groups and clinical demonstrations may be more useful than formal, didactic course work. It is important that we do not settle for what is easy to teach but do what is useful and meaningful. Cognitive knowledge and clinical skills are both important, but are not necessarily related. There must be further study of what constitutes meaningful continuing education for psychiatrists.

Temporal Disorganization and Inner-Outer Confusion in Acute Mental Illness

BY FREDERICK T. MELGES, M.D., AND ARTHUR M. FREEMAN III, M.D.

The authors found that changes in temporal disorganization covaried substantially and significantly with changes in Schneider's first-rank symptoms in 58 acutely ill psychiatric patients. Schneiderian symptoms reflect a confusion of inner and outer events; therefore, the findings suggest that difficulties in indexing events in time are closely related to problems in distinguishing experiences that arise within the self from outer experiences.

TEMPORAL DISORGANIZATION refers to alterations in the rate, sequential ordering, and goal-directness of thinking processes (1–5). A person can become temporally disorganized without being disoriented to clock and calendar time. Examples of temporal disorganization include racing of thoughts, difficulty keeping track of sequences, and indistinction as well as interpenetration of past, present, and future. These processes have been observed in patients with "functional" mental illness (6–9), but their possible relationship to symptom formation has been largely unexplored. In this paper, we will report a study of temporal disorganization in acutely ill psychiatric patients who were not disoriented to clock time and who did not have any other classical sign of coarse organic brain disease.

The focus of this study was on the relationship between temporal disorganization and symptoms of confusion of inner and outer events. To represent symptoms of inner-outer confusion, we chose Schneider's first-rank symptoms, such as experiences of alien influence, thought diffusion, and auditory hallucinations (10). Although Schneider originally proposed them as being "first rank" for the diagnosis of schizophrenia in the absence of organic brain disease, these symptoms of inner-outer confusion have been found in other illnesses, such as acute mania (11–13). We were interested not in diagnostic categories but in processes, i.e., the relationship of changes over time in temporal disorganization and symptoms of inner-outer confusion. A finding that such processes change together through time would suggest treatment strategies, since altering one of the processes might then influence the other (14–16).

The hypothesis was that in a sample of acute psychiatric patients (excluding organic brain syndromes) changes in temporal disorganization are correlated positively with changes in symptoms of inner-outer confusion. The rationale for this hypothesis has been formulated in detail elsewhere (1–6), but the essential consideration is as follows: If inner events such as memories, expectations, and emotions are no longer temporally indexed as linear sequences embedded within the continuum of inner experiences, then such inner events could conceivably be experienced as current phenomena that come from outside the person, much like present-time outer perceptions. Thus, the question we asked was: Are experiences lost in time also dislocated in space?

METHOD

Testing was performed by research assistants blind to the hypothesis who evaluated consecutive admissions to the psychiatric inpatient units of the Santa Clara Valley Medical Center on the day of admission after explaining the procedures and obtaining informed consent. Patients answered questions about orientation to time, place, and person and performed calculations; they were also questioned about illicit drug use and alcohol abuse for at least three days before admission. Those with organic brain disease or a recent history of drug abuse were excluded.

After the screening procedures, the research assistants tested 58 patients on the day of admission and again at the time of discharge (or transfer to another hospital) in order to obtain change data. The mean age of the sample, which was evenly divided as to sex, was 28.9 years (SD=11.8) and mean education was 14.1 years (range 7–22). Other descriptive variables are listed in table 1. The diagnostic breakdown was as follows: schizophrenia, N=41; mania, N=5, other psychoses (e.g., paranoid state), N=7; and neurotic-character and adjustment reactions, N=5. These diagnoses

When this research was done, Dr. Melges was Chairman and Dr. Freeman was Chief of Unit II, Department of Psychiatry, Santa Clara Valley Medical Center, San Jose, Calif. The authors were also on the faculty of the Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, Calif. Dr. Melges is now Professor of Psychiatry, Duke University Medical Center, Box 3812, Durham, N.C. 27710, and Dr. Freeman is Professor of Psychiatry, University of Alabama Medical Center at Birmingham.

The authors thank V. Moley, D. Johnson, D. Rogers, G.R. Lathrop, D.J. Savage, D.J. Lowe, M.D., and W.T. Roth, M.D., for their assistance and advice on this project.

3 to 5	13	22.4
5 or more	2	3.5

were made independently of the researchers by the ward psychiatrists according to the broad *DSM-II* categories listed above. There was diagnostic concurrence between the primary ward psychiatrist and an independent assessment by a psychiatric resident or another ward psychiatrist in 91% of the patients. Before the present illness, 77.6% of the patients had been regularly employed or going to school. At the time of admission, all patients were acutely ill, i.e., they required admission to a locked facility for emergency management. The average hospital stay was only 5.8 days (SD=3.0), which reflects the acute treatment and triage functions performed by this unit for highly disturbed patients in Santa Clara County. At the time of admission testing, all of the patients were acutely ill and 25% had received initial doses of psychotropic medication. By the time of second testing, 88% of the patients were receiving antipsychotic medications, usually in moderate doses (e.g., 20–30 mg/day of fluphenazine).

The tests consisted of inventory statements taken from previous research and refined in pilot studies with structured interviews to make them as clear as possible for acutely disturbed patients. The inventories were presented in random order, and the statements were read aloud by the research assistant with the patient looking on and also reading. Patients were carefully instructed and reminded to reply in terms of their experiences on the day of testing on the following scale: not at all, occasionally (1–2 times per hour), often (5–10 times per hour), frequently (more than 20 times per hour). Patients' understanding of this scale and of the inventory statements appeared to be adequate, since ratings by the research assistants indicated all patients were at least "reasonably reliable" except 2, who were of "questionable" reliability. In the lists of items given below, the last item in each component except number 5 for temporal disorganization is phrased in the direction of normality (and scored in the opposite direction) to help avoid response sets.

Temporal disorganization was measured by a total of 20 statements, derived largely from previous research (1–6), with 4 statements in each subcomponent.

1. *Rate-duration changes*: My mind seems to be racing. My mind seems to be going slowly. I'm unsure how much clock time has gone by (unless I look at a clock). My mind seems to be going at its usual rate.

2. *Tracking difficulties*: I tend to lose my train of thought. I forget what I've just said or intend to say. My mind goes blank at times. I can keep track of what I'm thinking about.

3. *Temporal indistinction*: My past and future seem to have collapsed into the present, and it is difficult for me to tell them apart. My past, present, and future seem all muddled up and mixed together. Sometimes I feel absent from the present, swept into the past or future as if I were really there. It's easy for me to tell whether something is a memory, a perception, or an expectation.

4. *Impaired goal-directedness:* My sense of self-direction seems to be impaired. I lose control over my thinking. It's hard for me to direct my thoughts to what I intend to think or say. My thoughts and actions are organized toward what I want to do or say next.

5. *Desynchronization*: My mind switches between speeding up and slowing down. I am having two or more trains of thought at the same time. Some of my experiences seem to have happened before in the exact same way. My mind swings back and forth in opposite directions.

The symptoms of inner-outer confusion were derived from Schneider's first-rank symptoms of schizophrenia and refined from other studies (10–13), with 4 statements in each of the subcomponents below.

1. *Auditory hallucinations*: I hear my inner thoughts spoken aloud. I hear voices outside my head arguing or talking about me. Voices comment on my actions at the time that I do them. All the voices that I hear come from myself or persons I can see talking.

2. *Experiences of influence*: I am made to feel emotions that are not my own. Outside forces put impulses into me. Forces other than myself make me do or say things that I don't intend. I myself am in control of what I do, think, and feel.

3. *Thought diffusion*: Thoughts that are not my own are put into my mind. My inner thoughts are broadcast to other people even when I don't speak aloud. Some outside force or person takes my thoughts away. My inner thoughts are contained within my head and nobody can read my mind.

4. *Delusional perception*:[1] Something strange is going on in the world around me. Unusual coincidences are happening to me that seem to have special mean-

[1] Careful reading of Schneider (10) suggested that uncanny coincidences of outside events referred to the self were central to his phenomenological description of delusional perception.

TABLE 2
Correlations Between Changes in Temporal Disorganization and Symptoms of Inner-Outer Confusion*

	Total Temporal Disorganization	Rate-Duration	Tracking	Temporal Indistinction	Impaired Goal-Directedness	Desynchronization
Total Inner-Outer Confusion	.73	.53	.57	.52	.57	.70
Auditory hallucinations	.54	.51	.44	.28	.35	.58
Influence feelings	.62	.35	.51	.45	.52	.62
Thought diffusion	.58	.35	.43	.54	.49	.50
Delusional perceptions	.55	.44	.42	.35	.42	.57
Somatic passivity	.63	.49	.49	.46	.51	.55

*Correlation coefficients greater than .25 are significant at the .05 level, those greater than .35 at the .01 level, and those greater than .44 at the .001 level (df=56).

ings for me and my future. Something I see or hear suddenly takes on a profound significance for me and my future. The coincidences that happen to me are just ordinary chance happenings, with no special meaning for me or my future.

5. *Somatic passivity experiences*: Somebody or something touches me even when nobody is around. Unusual sensations are put into my body. My body is controlled by outside forces. My bodily movements seem normally under my control.

Although most of the Schneiderian symptoms listed above can be conceptualized as inner-outer confusion, some of Schneider's symptom descriptions (e.g., thought-echo and delusional perception) may not be readily interpreted in this way. For the purposes of this research, compared to constructs such as diffusion of ego or body boundaries these Schneiderian symptoms investigated questions relevant to inner-outer confusion that were specific enough to be measured by scaled subjective report methods.

The total temporal disorganization score and the total inner-outer confusion score consisted of the sum of their respective subcomponents, with higher scores indicating greater psychopathology. For the data analysis, each subject was used as his own control to obtain difference scores between the first and second testing results in each test category, and then Pearson product-moment correlation coefficients between the changes were computed.

RESULTS

The hypothesis that changes in the degree of temporal disorganization are correlated positively with changes in the degree of symptoms of inner-outer confusion was confirmed (see table 2). The change correlation between the total temporal disorganization and the total inner-outer confusion score was .73 ($p<.0001$). The change correlations between the subcomponents of temporal disorganization and of inner-outer confusion were all significant at least at the .05 level; most were significant at the .001 level.

DISCUSSION

The finding of substantial, significant positive correlations between changes in temporal disorganization and concomitant changes in symptoms of inner-outer confusion suggests that these two processes are closely linked with one another through time. Just how these are interrelated is open to interpretation and further inquiry.

The finding of covarying changes over time in a clinical investigation such as this does not necessarily imply that there is a causal or mutually influential interaction between the variables. To study the relationship further, manipulation experiments are necessary to test whether inducing or treating one process will bring about changes in the other. We have already studied the induction of temporal disorganization in normal subjects through the use of THC. One of the earliest and most distinctive effects of THC is the alteration of time sense (17). Low doses of THC have been found to produce mild to moderate temporal disorganization but few, if any, symptoms of inner-outer confusion, whereas high doses of THC produced marked temporal disorganization and definite symptoms of inner-outer confusion (1, 3, 5). None of these subjects was globally disorganized or delirious in terms of being disoriented to clock or calendar time, place, or person. Another type of disorganization induced by comparable doses of alcohol in the same subjects was not associated with marked temporal disorganization nor with symptoms of inner-outer confusion.

In the THC experiments, temporal disorganization preceded the emergence of symptoms of inner-outer confusion; thereafter, the two processes covaried. In longitudinal clinical studies (1, 9), temporal disorganization (e.g., racing of thoughts, confusion of sequences, and timelessness) has been found to occur prior to the onset of symptoms of inner-outer confusion.

The most useful experimental design for studying this relationship may be to find some way of specifically treating temporal disorganization in order to test whether symptoms of inner-outer confusion might be

prevented or diminished by such a treatment. Whether such a treatment strategy would be at the social, psychological, or neurochemical level, or a combination of these, deserves exploration. Because temporal disorganization has been found to be related to problems with immediate or "working" memory (4, 5), it would be interesting to see whether treatments aimed specifically at enhancing immediate memory would correct temporal disorganization. If so, one could also test to see whether symptoms of inner-outer confusion could be prevented or diminished by this approach.

An enhancement of immediate memory might help restore the patient to what Minkowski (18) termed the "I-here-now" position so that he/she can distinguish the *now* from the *then*. This may prevent the patient from being engulfed by his/her own inner memories, expectations, and imaginations as if they were telescoped into the present, and responding to them as if they came from outside the self, much like present-time outer perceptions. Psychotherapeutic strategies also could be developed to help patients differentiate the present from the past or future. To quote Arieti (19), "we must try to reenlarge the patient's psychotemporal field. . . . Whereas the world of psychosis has only one temporal dimension—the present—the world of reality has three: past, present, and future." By helping patients to distinguish and reorder their experiences as past, present, and future, their experiences of inner-outer confusion may also be corrected.

Life Planning: An Educational Approach to Change

BY HUGH JAMES LURIE, M.D.

Life-planning methods that have emerged over the past several years offer alternatives to psychotherapy for the person experiencing the crises of mid-life and mid-career. The author describes several approaches to life planning and presents details regarding the implementation of life-planning methods.

> The daily pressures to act, to do, to decide make it difficult to stop and think, to consider, and to examine one's life goals, one's directions, one's priorities—the basic choices one faces in managing his own world.
>
> —Roy Menninger (1, p. 16)

NEW AND intriguing methodologies have emerged over the past several years which offer alternatives to the traditional therapeutic measures that have been used to help people cope with the stresses of mid-life. These stresses include a sense that one is on a treadmill in a career, that family and friends are growing stale, and that life is closing in.

Life-planning methods combine aspects of several disciplines, including education, educational psychology, and ego psychology. This paper will focus on life-planning formats that have been derived from these disciplines. In addition, I will discuss implementation strategies for life planning and the relevance of life-planning exercises for medical and other professional groups.

LIFE-PLANNING METHODOLOGIES

Management by Objective

Educational psychology has exerted a strong influence on organizational planning and development in recent years. This influence often takes the form of "management by objective" (MBO). MBO methods were taken from business administration theory, applied to the analysis of current organizational realities, and ultimately directed toward planning for short- and long-term goals. Some life-planning centers have translated these methods into a format that is "objective" and relevant to assessment and analysis of an individual's present life situation and establishment of new goals for the future. Although such methods were originally used primarily with women contemplating employment after years away from the labor market, they have been increasingly used with other groups, including physicians.

One life-planning center, the Individual Development Center of Seattle, uses a variety of exercises to illuminate different aspects of the individual's current life situation.[1] These exercises include detailed analyses in the areas listed below.

1. Influences that have shaped a person's self-image, including experiences in grade school, high school, and college; family and other interpersonal influences; introversion and extroversion; career; fantasies; and previous experiences in seeking employment.
2. A systematic analysis of work the participant has done (including volunteer work and hobbies) and work skills, specialized knowledge, natural abilities, and specific tasks accomplished.
3. Current life situation, involving assessment of activities that decrease or increase anxiety, destroy or build self-esteem, produce pleasure or pain, exhaust or energize, and narrow or expand horizons, as well as an analysis of values.
4. Current time expenditures, past goals, finances, friendships, health and energy, and potential or contemplated new goals.
5. Long- and short-term goals and an analysis of what they would mean for the participant and his/her family, economic situation, self-concept, and lifestyle.

A large amount of information is assembled through these exercises to use as the basis from which an individual can begin to change his/her life, e.g., career, time allocations, friendships, and finances. Each exercise is designed to be used in classes that are held weekly for six weeks; after the series, there is an individual counseling session.

"Students" are expected to complete weekly "homework assignments" that are labeled as such rather than as "therapeutic goals." Participants are asked to analyze in writing the issues assigned to them for each session; these responses are used as the basis for discussion, sharing, and peer consultation in small groups at the weekly sessions.

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Lurie is Clinical Assistant Professor of Psychiatry and Behavioral Sciences, University of Washington School of Medicine, Seattle, Wash. 98195.

[1]The center is located at 1020 East John St., Seattle, Wash. 98102; complete exercises and further information may be obtained from Ms. Alena H. Moris, Director.

A Personal Time Study

Roy Menninger has remarked that

> the important things in our lives are frequently deferred with some comforting but self-deceiving assumption that there will always be time tomorrow. . . . there is a high probability that your use of time and energy reflects serious imbalance within the life-space of each of you. . . . Time for one's self is discouraged, pleasure is deemed to be selfish, and one's own needs come last. (1, pp. 16, 17)

The need to allocate time and determine priorities—especially time for oneself—is crucial to successful life planning. This problem has been analyzed by different observers who (predictably) propose different solutions: Menninger (1) suggests that time allocation should be delegated to other people. An article in a popular magazine (2) suggests that individuals who have efficient personal filing systems and are organized will save time. The Individual Development Center believes that wasted and unproductive time often reflects failure to analyze and establish time priorities; this center has developed an exercise to facilitate establishment of time priorities in which the participant is asked to calculate the amount of time spent each week on a variety of activities, including sleeping, eating, paid work, volunteer work, driving and commuting, child care, family interaction, food preparation, entertainment, physical activities, education, and hobbies. Participants are then asked, "A week has 168 hours. What have you learned about your time scheduling?" Clearly, unless one gets down to specifics, talk about saving time is nonsense.

Values Clarification Techniques

Values clarification, a technique originally designed for teachers and their students (3), is a useful adjunct to life planning. One of the assumptions behind values clarification is that many people are unaware of their values and choices until they are forced to rank them in importance. "Practical people" like physicians often prefer to grapple with life planning by sorting out priorities in their favorite activities rather than struggling with more abstract concepts such as fantasies and roles.

Although values clarification exercises can be done on an individual basis, they appear to be particularly suited to groups in which a person can first assess his/her own values and then discuss them with a group of peers. I have used various values clarification techniques with groups of physicians, including psychiatrists, and I have been impressed with the degree of self-scrutiny and reassessment they often encourage within a brief period of time. Clarifying values is quite different from clarifying goals; many individuals can function adequately on a day-to-day basis despite being out of touch with their basic values. Values clarification is particularly useful before life changes such as retirement. The physician who is anticipating retirement in a Florida golfers' paradise may discover that he will seriously miss his friends, neighbors, and family, and that the allure of golf under sunny skies does not balance out the contemplated losses.

Projective Techniques

Life-planning exercises available from the National Training Laboratories of Applied Behavioral Sciences, Arlington, Va., include a variety of projective techniques designed to be used on an individual basis; results are then compared with those of peers. For example, in the "life on a line," the person is asked to draw the pattern of his/her life as if it were a fever chart. The person is then asked to label the highs and lows and to draw a line anticipating the pattern of the future. This exercise is particularly useful in identifying concerns and dissatisfactions with the current life situation (as well as the specific ingredients of "better times"). In another exercise, the individual is asked to write an epitaph for him/herself and then determine, with small-group consultation, how his/her current life situation supports or refutes these ultimate wishes.

Role and Goal Priorities

Some life-planning exercises, including those of the National Training Laboratories, ask the participant in a workshop to identify and rank his attributes and roles. One exercise is, "Think of all the answers you can to the question, 'Who am I?' " There should be at least 20 answers; often, there are more. The answers might include one's role in life, appearance, or one's beliefs and feelings. The individual is then asked to arrange the list in order of importance and to discuss his/her top choices.

In another exercise, the individual is asked to rank a list of 11 goals or life values in terms of the present, as well as what he/she would like the future to contain. Some of the items on the list are leadership, prestige, wealth, independence, security, and duty. The lists are then discussed in a group format. This exercise offers a more structured method of goal assessment than the "Who am I?" exercise.

Video Stimulus Materials

Middle-age crises seem remote and the need for life-planning seems nonexistent to some professional groups. This is particularly true for young medical students who face immediate, pressing goals such as graduate education, exams, and postdoctoral training. One effective way to stimulate medical students' recognition of the need for life planning is to show provocative videotaped vignettes that portray (with appropriate affect and anguish) physicians who are experiencing mid- or late-life crises (overwork, depression, disillusionment, marital conflict). This "visual assault" seems to be one of the only ways in which to capture the interest of such a difficult and well-defended group before a crisis actually occurs. Although many younger physicians today are obviously capable of elaborating comprehensive life goals, a number of physicians

of all ages become locked into narrow and limited goals that look more toward material acquisition than toward emotional needs and satisfactions. Videotaped vignettes, produced by the author, have been used successfully with students in a number of different medical schools as a basis for discussion and a prelude to life planning. These vignettes have also been used with a group of psychiatrists at an annual meeting of an American Psychiatric Association district branch to stimulate discussion and personal introspection about the life-styles of psychiatrists, which often include isolation, depression, and psychological morbidity. I have also used them productively for life-planning discussions at an APA colloquium on postgraduate education and at several national conferences focusing on practicing family physicians.[2]

Organization and Implementation of Life Planning

Life planning can be like New Year's resolutions: without a specific scheme for their execution, plans and dreams may just disappear. Methods of implementing life planning range from those which produce little anxiety to those designed to stimulate the individual to take immediate action. Several possible approaches are listed below.

Individual Counseling

By definition, individual counseling for life planning involves a meeting between a client contemplating a change in career or life-style and a skilled, informed counselor who can assist in discussing the options. Advantages include convenience and privacy; many individuals may be reticent about discussing fantasies and plans for change with peers for fear of ridicule or even retribution. Major disadvantages are the lack of peer feedback and support and the overreliance on the "expert" rather than the opinions of colleagues.

A felicitous compromise can exist when individual counseling for life change is an adjunct to a larger mental health training program. The Menninger Foundation training program on personality development often included individual elective life-planning sessions. Many of the individuals attending these programs, most of which were directed by Dr. Herbert Klemme (4), already had a high level of sophistication and understanding about the possible needs for change in their careers or life-styles (participants included physicians, corporation executives, and city managers). The life-planning counselor—in the context of a cognitive and affective learning experience about personality development throughout life—was able to help the participant identify and formulate his/her own life and career goals and changes and provide a helpful push toward implementation.

[2]The vignettes, titled "Human Experiences of the Practicing Physician" are available through the Mental Health Media Project, Department of Psychiatry and Behavioral Sciences, University of Washington School of Medicine, Seattle, Wash, 98195.

The Educational Course Approach

A group program with a classroom and course format may be seen as less threatening and more familiar to many individuals than would an experience with overtones of a therapy group. The unique advantages of life planning conducted within an educational format include the structure of cognitive experiences and exercises, the support of fellow students, the period of time between assignments, and the greater likelihood that the participant will carry out his/her plans because they have been put in writing with peers as witnesses.

In any counseling format, the skills of the leader in organizing the group and conducting exercises to encourage individuals to share their concerns and hopes is critical to success, as is the model of openness the leader presents. The teacher may use a variety of "games," such as three-person group consultations, collage techniques (cutting out magazine pictures describing different aspects of one's life and showing them to the group), or cognitive methods. The educational course approach encourages a climate of self-inspection, cognitive understanding, and structured fantasy and can provide the best entry into life planning for many individuals. The setting can be either a classroom (with comfortable seating) or an atmosphere that provides more flexibility in seating to accommodate the ebb and flow of small and large groups and the need for each group or individual to be separate at times.

Therapy and Support Groups

Therapy groups rarely include specific goals for life planning, but some support groups do include an opportunity for individuals to discuss and receive feedback from other members about current life and career goals and problems and their evolution. Some therapy groups evolve into life-planning and reassessment groups; in others, this aspect is part of the original design. Such groups can be included in professional meetings. The Network for Continuing Health Educators (a group originally organized under APA auspices) includes support and life reassessment activities as part of its semiannual training workshops. Another small group of mental health educators who met initially with a highly skilled leader to assess how they were managing their mid-life "transitions" now meets from time to time on a leaderless basis to ask the same questions and to give each other support and feedback.

There is always the danger that the group will become coercive or that there will be an expectation of change in an individual member that he or/she may not be prepared to make. Despite these potential difficulties, when a group of individuals is willing to invest in the undertaking, the creation and continuation of a support group to mediate career and life-style change is feasible. A relaxed setting, away from the distractions of the city and career and conducive to self-revelation, listening, and planning, is optimal for

groups meeting for several days of life-planning activities.

One-Day Consciousness-Raising Sessions

One-day workshops can often be helpful for professionals who are in a rut but are not sure what the problem is. Workshops can help the participants to crystallize issues and can raise affect and mobilize curiosity and interest in the process of problem solving and self-scrutiny. A particularly successful workshop, entitled "What You Have Always Wanted to Know About Doctoring But Were Afraid To Ask," was held in western Pennsylvania several years ago for physicians and their families. The workshop, guided by a cadre of skilled group leaders, moved physicians and their spouses and children, separately and with other family members, through a series of rap group experiences. There was a great deal of intense discussion by the physicians and their families about the hazards of medical life and of being part of a doctor's family: the isolation, the harassment, the lack of opportunity for recreation, and the progressive alienation of spouses and children from the excessively busy doctor. Wives often confessed that this was the first time they had ever really "let their hair down" and acknowledged their pain and frustration. As a result of this experience, several families made a commitment to examine their life-styles and to implement specific changes in current activities and future goals.

Atmosphere is a crucial factor in the one-day consciousness-raising session. The setting must be comfortable and relaxed, and recreation should be available either before or after the conference. Although they resemble encounter groups in some ways, such workshops raise more focused issues; thus, the affect that is mobilized is less frightening to participants than an experience without explicit expectations, time limitations, and agenda. On occasion, consciousness-raising sessions have led women's auxiliaries of medical societies to have more intensive life-planning experiences for themselves and their spouses. The desired outcome is for the participants to take more responsibility for acknowledging, sharing, and using their perceptions of their own needs rather than simply submitting to the desires of the "professional" in the family.

Life Planning for Couples

Studies suggest that half of physicians have been in "bad" marriages (5). An interview in the *Hospital Tribune* in 1974 with several knowledgeable psychiatrists—Drs. James Evans, Herbert Modlin, and James Karding—suggested that doctors' wives often feel second rate and neglected by their busy husbands and believe that most of the important marital decisions are made by the "important," i.e., professional, spouse with little reference to the needs of the "less important" spouse. The advantage of involving couples in life planning is that it may provide a means to preserve relationships and marriages while allowing both members of the couple to change and grow. A couples group can be an extended experience (e.g., weekly meetings) or an intensive experience for a weekend or week. Couples workshops can use the traditional format of a therapy or encounter group or include more cognitive or structured experiential exercises. The motivation for attendance at such a group is often a recognition that the marriage is floundering or intimacy is dying. The group may focus on ways to enrich the marriage or increase intimacy between the partners. As is the case in other group experiences, there is a danger that "pseudo-intimacy" may result, and that a "group high" may be seen as a substitute for working out the basic problems in the relationship.

Life-Style Experimentation

Some individuals discover their goals after they try them out. This may include experimentation with different ways of relating, with various roles, and with new styles of professional practice. Opportunities to experiment with a new life-style are available through intensive and often rather lengthy human growth experiences such as those provided by some of the summer programs at the National Training Laboratories of Applied Behavioral Sciences at Bethel, Me., or at growth centers such as Esalen in Big Sur, Calif. Some participants, during the experience, can adopt new identities, new ways of relating, and even new names.

There are several means of career experimentation. One method is the sabbatical: for a physician this works best if he/she is associated with an institution such as a health maintenance organization or a prepaid health plan. For example, one physician changed from a primary care role to teaching at a local medical school for six months. At the conclusion of this trial career change, he was able to assess whether the new job provided enough compensation, e.g., less pressure and more time with his family, to compensate for the decrease in income. Another method involves a new commitment to an intensive volunteer or consultative experience for a specified period of time, following which the individual can evaluate the satisfactions and drawbacks of the new career and decide whether it should be pursued in earnest. It is often easier for an individual to reach conclusions about implementing change if he/she can discuss the meaning of the experience with someone else and develop a cognitive understanding rather than simply mulling it over without feedback.

CONCLUSIONS

Life planning is available in a variety of formats, ranging from classes to individual counseling and from highly structured exercises to projective experiences.[3] Life-planning activities may be tailored to the individ-

[3]A national organization of life-planning facilities is Catalyst, 14 East 60th St., New York, N.Y. 10021.

ual needs of the person, to his/her particular learning style, to the time available, and to his/her goals (e.g., career change or reestablishing marital intimacy). Many factors about the ways in which individuals grow and change are still unknown; Sheehy's book (6) about individuals experiencing life change is a beginning attempt to describe some of these variables. The person's profession may be relevant to these factors. Does a family physician who often has to compartmentalize his day into brief segments learn best through a life-planning experience that is similarly compartmentalized (7)? Does the architect who often must mull over a project and ideas for weeks at a time learn best if his/her life-planning experience is correspondingly deliberate, reflective, and gradual? Despite our lack of knowledge, one thing is clear: life planning for many people caught in a developmental crisis offers an alternative to psychotherapy and can be a useful tool for helping the individual who does not wish to define himself as "sick" to get better.

Evaluation of a Psychiatric Clerkship By Videotape

BY ARTHUR T. MEYERSON, M.D., ALAN WACHTEL, M.D., AND JOHN THORNTON, PH.D.

The authors used a videotape-based objective examination in general psychiatry to assess the clinical competence of medical students who had completed their third-year clerkship. The test has been shown to be a reliable, valid measure of clinical competence. Subjective faculty grading related positively to test scores. Students on one ward had significantly lower overall test scores, with particularly low scores on clinical judgment questions. However, faculty grades for these students were not significantly different. This suggests that the faculty was unable to assess the relative efficacy of its own teaching. The test can provide objective assessment of student clinical competence and is a means of program evaluation.

THE NEED FOR standardized, objective measures of clinical competence in psychiatry has been well documented (1–3). Such measures are necessary to objectively evaluate clinical competence of students and to assess the efficacy of student training programs.

The use of audio and visual aids to examine the clinical psychiatric competence of medical students gained prominence in 1958 and 1960 with the work of Gurtsma and Stoller (4, 5), who used filmed interviews as a clinical stimulant for a series of written, scaled descriptions of the patient's behavior and psychodynamics. In 1961 Saltzman and Goldstein (6) used an audiotaped patient interview and had students rate 303 psychiatrically relevant statements on a 7-point scale. The subjects (faculty, residents, interns, and four classes of medical students) demonstrated the same correlation of performance with level of training as previously reported by Gurtsma and Stoller (5).

Goldstein and Saltzman (7) concluded that "performance on clinical judgment tasks was significantly related to [the] student's overall academic performance, but showed no relationship . . . to rating of clinical competence made by his supervisors . . ." Therefore, they concluded that "one cannot accurately predict the student's actual clinical performance on the basis of his scores in the clinical judgment test."

Using written case material, Langsley (8) in 1962 compared performance of second-year medical students from four different schools on a multiple choice examination.

Monroe (9) in 1965 used filmed interviews with a multiple choice examination, dividing his test into three categories: psychotherapy, clinical evaluation, and knowledge. He divided clinical clerk performance into upper, middle, and lower thirds and "in a rough comparison, it was reassuring to find that in only 10 of 85 students was there marked disparity between clinical performance on the second-year examination and their performance during the third-year clerkship."

Turnblad and associates (3) developed an examination using a videotaped psychiatric interview followed by a series of statements designed to measure "a combination of observational skills, understanding of psychiatric knowledge and theory, and (on some items) a degree of empathic understanding." In four classes of medical students Turnblad and associates found a significant change between the preclinical medical students, freshmen, and sophomores but found no change when they compared the sophomores (i.e., before clinical experience) with juniors and seniors who had completed clinical clerkships. Although they had planned to develop an examination "to simulate a clinical task and measure clinical skills," Turnblad and associates (3) concluded that they had found "a useful instrument for evaluating the knowledge and observational skills of preclinical teaching."

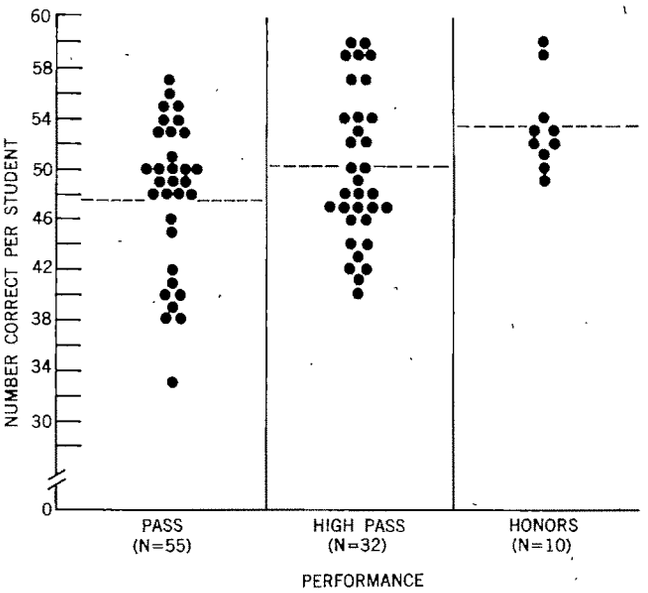
Miller and Tuppin (10) used a video-based examination to evaluate performance of students taking the SAID (Systems Analysis Index for Diagnosis) program. This was an evaluation of a preclinical course and involved pre- and posttesting. Thus, program evaluation, as well as student evaluation, has been a goal of this developing field.

Recent work by Dowaliby and Andrew (11) in 1976 showed a positive correlation between National Board Examination performance and faculty evaluation of clinical competence. They suggested that, on the one hand, "faculty members are able to make discrete judgments about students on more than one dimension" and that, conversely, an objective exam can correlate with faculty clinical performance rating. The National Board of Medical Examiners Examination, Part II, uses no audiovisual aids.

Dr. Meyerson is Associate Professor of Clinical Psychiatry, Mount Sinai School of Medicine, 5th Ave. and 100th St., New York, N.Y. 10029, where Dr. Thornton is Assistant Professor of Statistics. Dr. Wachtel is Fellow in Psychiatry, New York Hospital–Cornell Medical Center.

The authors wish to thank James Ryan, M.D., Department of Psychiatry, Columbia University College of Physicians and Surgeons, for the use of some tape material and questions.

The validity of these instruments is frequently established by faculty agreement on correct answers to the test questions. Test reliability has been largely unexplored. Langsley (8) did use a split-test reliability to assess his instrument.



This paper focuses on the nature of the study examination, its reliability and validity, a comparison of the test results with the subjective evaluation of the clinical clerks by the faculty of the department of psychiatry, and the use of test results for program evaluation.

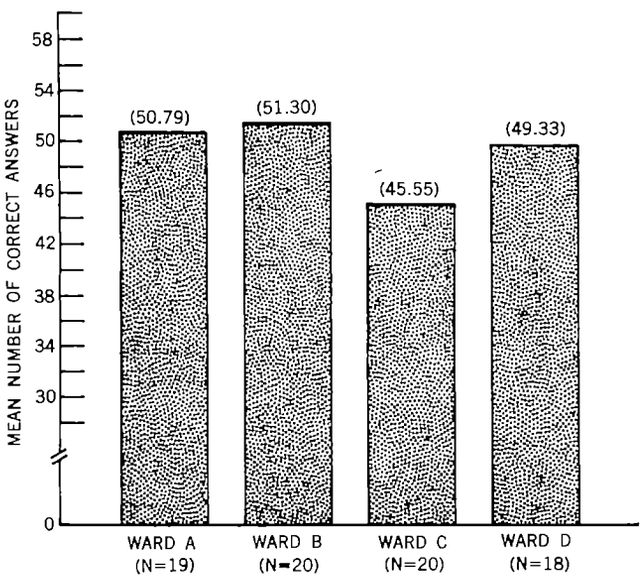
METHOD

A videotape-based test of clinical competence was given to 77 third-year medical students at the end of each of their 6-week clerkships in psychiatry. The test consists of four major taped student-patient interviews and four clinical vignettes. The patients interviewed suffered from the following illnesses (diagnoses from *DSM-II*): psychotic depressive reaction; schizophrenia, paranoid type; organic brain syndrome, acute—secondary to toxic ingestion; organic brain syndrome, chronic—secondary to senile dementia; and chronic alcoholism. The test consists of 73 short-answer, multiple choice questions. Among the several types of questions are true or false, best answer, and best combination of answers. Questions are directed toward three major areas: observation (e.g., Which of the following signs is displayed by this patient?); clinical judgment (e.g., Which of the following statements are correct in regard to criteria for this patient's hospitalization?); knowledge (e.g., Which of the following are side effects associated with phenothiazines?). Informed consent was obtained from all the patients who were interviewed. Students were informed that this test was experimental and were assured that the results would in no way influence their clerkship grade. They were asked not to discuss the procedure and content of the test with classmates who were to take it at a later date. No time limit was imposed and all students completed the test. Only research personnel were aware of the students' test grades and the content of the test.

The student's grade for the clerkship was derived from the unit chief, the unit chief resident, all inpatient and outpatient preceptors, and all course instructors, all of whom were required to globally rate several major items (knowledge, interest, participation, attitude, curiosity, etc.) and to fill out a comprehensive and detailed rating form of more than 30 items on a 5-point scale, including amount of reading, personality, ability to relate to staff and patients, etc. A meeting of all major teaching staff was held at the end of the clerkship and verbal reports were made and recorded. The director of the clerkship wrote a summary report and grade based on the aforementioned sources. A student was assigned one of four grades—honors, high pass, low or routine pass, and fail. One student failed during the study.

FIGURE 1
Relationship of Subjective Faculty Grades to Students' Test Scores*

*F=3.7; p<.05.



RESULTS

Test reliability as calculated by the Kuder Richardson 20 (KR-20) (12) on the results of 77 students was .6651. All other statistical analyses do not include 3 students who either failed (N=1) or received low or routine pass (N=2) for the clerkship. However, no reported results change significantly if these 3 are included. Figure 1 shows the relationship of subjective grades assigned by the faculty to test scores. Out of a possible 73 correct answers, the mean scores were 47.88 correct answers for the low-pass group, 50.16 for the high-pass group and 53.30 for the honors students. As shown, these results are significant ($p<.05$; Fisher exact probability=3.70).

Figure 2 displays the students' test scores by ward assignment (labeled A, B, C, and D)—19 students were assigned to ward A, 20 to B, 20 to C, and 18 to D. These assignments were totally random. Each clerkship group is listed alphabetically and then assigned a ward in rotation. Figure 2 demonstrates that the test performance of the ward C students was below that for the entire group of low-pass students ($F=3.89$, $p<.025$). This remains true even if the one student who failed is excluded. An examination of ward C students' performance on the three subsections of the test reveals that this group of students did not significantly differ from the others on knowledge or observation questions, although a trend appeared ($p<.1$). However, on clinical judgment items, ward C students differed significantly from the whole group ($p<.025$).

Table 1 represents an examination of the subjective faculty grades given by all four wards to their students. There is no significant difference between wards.

FIGURE 2
Analysis of Students' Test Scores by Ward Assignment*

*F=3.89; p<.025.

TABLE 1
Subjective Faculty Grades for Students on Four Wards

Grade	Ward A (N=19)	Ward B (N=20)	Ward C* (N=20)	Ward D (N=18)	Total (N=77)
Honors					
Expected**	2.47	2.60	2.60	2.37	
Given	1	4	2	3	10
High Pass					
Expected**	7.90	8.31	8.31	7.48	
Given	10	4	8	10	32
Pass					
Expected**	8.64	9.09	9.09	8.18	
Given	8	12	10	5	35

*Ward C, the ward with low test results, came closest to the expected grades (χ^2=7.90, n.s.).
**Obtained by taking 10/77 of students on ward for honors, 32/77 for high pass, and 35/77 for pass.

Ward C, in particular, came closest to the expected values (χ^2=7.90, n.s.).

DISCUSSION

The reliability of the test instrument is a significant issue in all studies such as this. Few references to formal assessment of reliability of test instruments of student clinical competence in psychiatry are available (8, 11). Dowaliby and Andrew (11) recently reported a study in which faculty grades were compared with test scores on the National Board Examination, Part II, after a training clerkship for paramedics. In that study the results of four of the six Board exam subsections correlated significantly with faculty evaluations of the students. The KR-20s of two of these four were .61 and .49. These are well below the level achieved by our test (KR-20=.6651). Test reliability is probably not as high as one would prefer for a test of objective knowledge. However, the KR-20 is a function of the number of questions and videotape, which reduces available time, is a limiting factor. The KR-20 provides an estimate of the reliability of a test. The equation has been derived in various ways by using sets of assumptions and different techniques (12–16). A basic assumption used to develop the KR-20 is the homogeneity of the function being measured by the test items. Because this assumption is intentionally not satisfied by the present test, with its focus on observation, knowledge, and clinical judgment, one cannot place too much emphasis on the apparent value obtained for the KR-20. The .6651 value may be viewed as a lower bound (lower limitation) of the true reliability of the instrument (16).

Validity, as stated before, is often equated with faculty agreement on an instrument's correct answers—"the test was also given to a group of faculty to test its validity" (3). Our instrument was submitted to several senior faculty members (not directly involved in the clerkship), and correct responses were verified. However, the use of faculty assessment of the correct answers provides no measure of the internal consistency of an examination or whether it measures what it was intended to measure. It merely provides a statement that the faculty agrees on the correct response to any one question.

The correlation of student test grades with faculty assessments ($p<.05$) strengthens the proposition that the current test is a valid reflection of the faculty's goals for the clerkship. A similar correlation was noted previously by Dowaliby and Andrew (11), although not with medical students. However, Goldstein and Saltzman (7) found no such correlation. Turnblad and associates (3) approached the question of the usefulness of an objective instrument independent of the clinical setting that used media and not real patients to measure medical student clinical competence. Turnblad's study did not attempt to correlate faculty assessment with test results. Our study does not directly compare students at various levels of experience. However, the instrument's capacity to distinguish student performance levels on questions of clinical judgment after different clerkship programs (the 4 wards) ($p<.025$) further strengthens its validity as a measure of clinical competence.

The notion that a test can substitute for some aspects of faculty evaluation, particularly of attitudes and ability to relate to patients and staff, is not the focus or conclusion of this study, nor is it a belief of ours. In this study direct observation of students offers invaluable insights. However, evaluation procedures involving direct observation of students can become cumbersome and may require using the same patient for many students to achieve standardized results,

multiple faculty observations, and a great deal of time; also, it would depend on questionable interrater reliability. This videotape-based test allows for distinctions in student performance on clinical judgment items. Thus, our data do not support Turnblad's critique of the capacity of videotape tests to assess clinical judgment based on the student role as a passive observer of a videotape as opposed to performance in the actual clinical setting.

The low test performance of the students on ward C ($p<.025$) is not reflected by any lowering of their faculty evaluations. Thus, the test permits a singularly objective assessment of faculty effectiveness regarding both training and student evaluation. This finding is further supported by ward C students' low performance on clinical judgment questions ($p<.025$) in contrast with the other teaching units. Thus, major support for the hypothesis that a test offers an opportunity not offered by subjective approaches for program and faculty assessment lies in the lack of a significant difference between ward C students' subjective faculty grades and faculty grades given students on the other wards. The fact that many schools train student clerks in a variety of hospitals, not just different wards in the same institution, suggests the possibility that variance in program success may be a virtual inevitability. Thus, testing as in this study seems clearly indicated.

CONCLUSIONS

Our use of the videotape-based test continues the efforts of others toward establishing a statistically reliable clinical examination in psychiatry. The use of analysis of variance and a standard test of reliability (KR-20) permitted a comparison of our findings with those of others, which has proven difficult in this area in the past. In addition, the instrument fulfills Turnblad's goals: "it is important that our assessment methods be reliable, that they validly measure desired objectives, and that they be efficient in the sense that they can be applied to large groups in a limited period of time" (3). The increasing pressure for objective evaluation of teaching programs and certification of professional competence renders further efforts in this direction essential.

In Defense of Community Mental Health

BY JACK ZUSMAN, M.D., AND H. RICHARD LAMB, M.D.

Initial enthusiasm for community mental health has given way to a barrage of criticism, much of it deserved. Originated to deal with abysmal conditions in state hospitals, community mental health focused instead on primary prevention, political activism, and the mildly mentally ill. The authors propose a return to the original fundamentals, stressing that the highest priority be given to community treatment and rehabilitation of the severely mentally ill.

THE ENTHUSIASM OF THE 1960s about community mental health has given way to a barrage of criticism from many different quarters, particularly from senior academicians (1–7). Further, there have been severe cutbacks in funding of training and services, especially at the federal level. Although the Community Mental Health Center Amendments of 1975 expanded the scope of community mental health centers and the services they should provide, this legislation has not been accompanied by any significant increase in funding.

Disillusionment is evident, even among former enthusiasts. Few among the leadership of the mental health professions are now inclined to defend, in whole or in part, the programs and theory embraced so enthusiastically just a few years ago.

Many criticisms of the community mental health movement have been well deserved, particularly those related to the failure to serve the many thousands of severely disabled long-term psychiatric patients who have been discharged from state hospitals (8–10). It has become increasingly apparent that society has chosen the easy and cheap way out: instead of providing these patients with the community treatment and rehabilitation they need, they have been placed in community settings where they live impoverished lives that resemble their experiences in the state hospitals. Community mental health has also been accused of pursuing its own interests, namely, meeting the financial, prestige, and power needs of the professionals in the field, while allowing the seriously ill patients to whom it promised so much to suffer neglect, poverty, and disability. Only recently have psychiatry and community mental health leaders begun to express concern about the problems attendant on deinstitutionalization.

Dr. Zusman is Clinical Professor and Dr. Lamb is Associate Professor, Department of Psychiatry, University of Southern California School of Medicine, 1934 Hospital Place, Los Angeles, Calif. 90033.

There has been much said and written by those working in community mental health about the value and potential of prevention. It was often implied (and sometimes promised) that the techniques of prevention would result in a significant reduction of mental illness and would eventually drastically reduce the need for conventional treatment because there would be so few patients (11, 12). Although preventive efforts in the form of consultation to community agencies such as schools, welfare departments, the police, and other caretakers have been popular and probably useful, the promised eradication of mental illness and/or social problems has not been forthcoming. Elaine Cumming (1) pointed out that the effectiveness of popular strategies for the primary prevention of the major mental illnesses has not been tested and that these strategies remove needed manpower from the treatment of the mentally ill. The overselling of prevention has probably been a major factor in causing people to become disillusioned with community mental health.

Still others (2, 3) have criticized community mental health for turning away from psychodynamics, psychotherapy, and meaningful interactions with patients. Although such criticism overlooks some of the basic origins, strategies, and components of community mental health, it is true that the importance of individual psychodynamics is frequently neglected in community mental health. For instance, aftercare programs consisting primarily of medication and a minimally stimulating environment are often provided routinely to every patient regardless of individual characteristics and needs. Even when relationships between staff and patient are good and there is close involvement, the understanding of the patient and his/her problems is often superficial and not based on individual study of the patient.

Some have attacked community mental health because "it has branched out well beyond mental illness into problems that it is not especially qualified to handle—community, national, and international affairs, poverty, politics, and criminality. In each of these areas, we have responsibilities as citizens and human beings; we have yet to demonstrate any special competence as psychiatrists" (4, p. 962).

A number of observers have attacked the whole policy of deinstitutionalization. Arnhoff (5) cites studies which show that community treatment is no better than hospital treatment for acutely psychotic patients,

either in short-term or long-term effects, and that community treatment has the additional disadvantage of placing a burden on relatives and the community; this burden is rarely negligible and in some cases intolerable. Arnhoff is concerned about the effects on children who are coming into greater contact with psychotic patients, both acute and chronic, who formerly would have been hospitalized. He points out that follow-up studies tend to reveal distressingly high percentages of marginal or poor adjustment, unemployment, and, for many, a subsequent need to return to the hospital and remain there. Arnhoff also worries that psychotic patients in the community will have a higher rate of procreation, produce more schizophrenics, and in many cases will be unable to provide adequate parenting for them.

In the early days of community mental health, there was much talk of the usefulness of blurring of professional roles and reducing the differences in both function and status among various staff groups. Psychiatry has suddenly awakened to find much of its power, prestige, and prerogatives being forcefully taken over by professionals from other disciplines and even by paraprofessionals. Community mental health gets the blame for this, and, in fact, such an egalitarian philosophy has been most widely articulated and put into practice in community mental health.

Still another criticism that is widely held but rarely aired in print is epitomized by the following:

> The [Federal] Office of Management and Budget is discovering inefficiency, waste, and vacuous promises, all right—not in good laboratories and clinics (although those will suffer from the cutbacks) but among the neighborhood storefront clinics, the funded "advocates," and other strange ad hoc "institutions." In the ballyhoo of the power struggles between minority political cadres and medical school administrators, nobody is served and potentially serviceable facilities have been destroyed. Lincoln Hospital, the Temple University Community Mental Health Center, the Boston City Hospital Drug Program and the Harvard Psychiatric Program at Boston City Hospital are just a few famous examples. Although the radical concerns are not as hot as they once were, and the street activists have quieted, they left a heritage of egalitarianism and complex jerry-built bureaucracies. The clamor for communities to determine their own health care delivery needs and to control the services still reverberates across the land. I, for one, hold the community psychiatry movement in no small way responsible for the current debacle—armchair philosophy and vague, untested notions are of no use in designing and running programs that cost hundreds of millions of dollars. (6, p. 1138)

Program evaluation has been proposed as one of the means of solving the problems of community mental health, but meaningful evaluation and quality control are rare in community mental health (13). Where such evaluations have been completed, administrators disregard them because of strong political, professional, and bureaucratic pressures to resist change.

Having acknowledged that these criticisms are not without merit, we must ask ourselves three crucial questions: What is the primary mission of community mental health? Has it really failed? What, if any, should be its future course?

THE PRIMARY MISSION OF COMMUNITY MENTAL HEALTH

In our view community treatment of the severely mentally ill is the raison d'être of community mental health. Perhaps the most important factor leading to the development of the community mental health movement was the concern about the abysmal conditions of treatment and life for patients in large state hospitals. These conditions were studied, documented, and publicized by Albert Deutsch in *The Shame of the States* (14) but were also of great concern to mental health professionals and their organizational leaders. A determination to bring about major improvements resulted.

Community mental health, to the extent that it grew out of the report titled *Action for Mental Health* by the Joint Commission on Mental Illness and Mental Health in 1961 (15), was intended to shrink large state hospitals by developing community alternatives, reduce the need for new admissions by the same means, and cover the country with community mental health centers that would provide a wide variety of services for patients who either had been in or would have had to be sent to state hospitals.

Even where hospital conditions were adequate, psychiatrists realized that most patients were capable of more than a life characterized by custodial care in an institution. A basic tenet of community mental health is that the treatment and rehabilitation of the long-term and seriously mentally ill can best be done in the community and not in large hospitals far removed from home (15). Implicit in such an approach is the concept of continuity of care not only between hospital and community but also within the community services.

A basic concept in community mental health is that behavior is affected, and in many cases determined, by the psychosocial-cultural milieu. In addition to understanding the intrapsychic conflicts of patients, we must understand their sociocultural backgrounds, adaptive capabilities, community supports, and social and family pressures. Armed with this knowledge, we can then provide treatment, rehabilitation, and support to deal with problem areas and to build strengths. Thus the community psychiatrist is involved not only with his patient but with his patient's milieu.

It is useful and important to consider which aspects of the contemporary community mental health movement were not among those originally propounded and therefore lack the foundation of years of concerned demonstration and testing. Among these latecomer elements are the ideas that many forms of mental illness are preventable, particularly by social changes, that effective comprehensive treatment and rehabilita-

tion of the seriously mentally ill in the community is less expensive than residential treatment, that the handicap of minimal theoretical and clinical training in treatment of the mentally ill can be overcome by membership in the same minority sociocultural group as the patients, and, finally, that mental illness inevitably results from, is tied to, or even is synonymous with deplorable, undesirable, or impoverished social conditions.

HAS COMMUNITY MENTAL HEALTH REALLY FAILED?

In our view, there has not been a failure of community mental health per se, but rather a failure to focus on the basic mission of community mental health. Only limited aspects of the original conception have been implemented, while the interest of most workers has gone off in other directions.

The major emphasis on reducing state hospitalization by administrative fiat without a corresponding effort to implement community treatment and rehabilitation of the long-term, severely mentally ill has not resulted from a lack of knowledge—effective community treatment techniques have been demonstrated and reported for a number of years (16). Instead, community mental health has tended to focus on treating the "healthy but unhappy." Considering the amount of manpower and funding available, an inordinate amount of effort and publicity have been put into primary prevention and social and political activism rather than direct service.

THE TURNING AWAY FROM COMMUNITY MENTAL HEALTH

We believe that community mental health has not been given a fair trial. The needs, originally so pressing that it was felt the structure of the national system of mental health services had to be revamped, are now just as pressing, but few political or professional leaders have made an all-out effort to meet them. A reasonable course of action would be for mental health professionals in general and psychiatrists in particular to move to meet these needs by putting into practice the basic concepts that still seem so promising. Instead, we see psychiatrists, especially those in academic settings, turning away from community mental health. A tendency exists to see mental illness as a collection of symptoms for which we need only select the right drug or as a biochemical disorder awaiting the discovery of the magic bullet that will cure the otherwise hopelessly ill (as if mental illness did not manifest itself in complex distorted interactions among human beings—interactions that can then lead to severe, permanent disability despite the disappearance of the original illness).

Why has this happened? Although we do not presume to analyze the motivations of any of our colleagues or of entire professional groups, we think the following factors are involved. First, professionals in community mental health settings have run up against the demands, not always reasonable, of community groups. These groups often see professionals as adversaries and as nonresponsive to the needs of the mentally ill. A similar situation exists in the attacks on psychiatrists as enemies of civil liberties. Having acquiesced to pressures to take on a social guardianship role, psychiatrists are surprised to find themselves accused of depriving persons of their civil rights. Thus many psychiatrists have been stung by such criticisms, which are at variance with their own self-images as physicians primarily concerned with the welfare of their patients, and have withdrawn to private practice or the academic ivory tower.

Another factor has been our disillusionment with the results of social and political activism and our realization that not everyone, and at times almost no one, regards us as the experts we think we are. There has been keen disappointment both within the professions and on the part of the public in our inability to reduce mental illness significantly by preventing it.

A further source of frustration has been the challenge to psychiatry from other disciplines and a feeling that in the area of community mental health the psychiatrist runs the risk of losing his status, his power, and even his high income. It is no wonder then that having ventured forth and tested the water in the community and having found it cold and uninviting, many of us have retreated to more scientific and academic pursuits.

RECOMMENDATIONS

Despite the difficulties of working in community mental health settings, our profession must not shrink from the task. It is time for a major rethinking of the community mental health movement and a return to the original fundamentals. There should be an emphasis on and high priority given to community treatment and rehabilitation for the severely mentally ill. A reasonable balance should be struck between direct and indirect services. Thus while still providing preventive and consultative services (we hope those with effectiveness that has come closest to being unequivocally demonstrated), we must retain a major emphasis on direct services for those groups in greatest need of psychiatric skills.

There has been important and exciting research in recent years in the biochemical and physiological bases of human behavior. Psychiatrists have every reason to be enthusiastic. Likewise, new drugs such as lithium have given new meaning to the refinement of psychiatric diagnoses; with drugs specific for affective disorders there is added reason to diagnose them correctly and differentiate them from the schizophrenias, and with the recognition of the serious side effects of

the antipsychotic drugs we have a mandate to develop our knowledge about these drugs and find more effective and less harmful ways to administer them. However, this research does not mean that we should decrease our interaction with our patients and no longer be concerned about the social elements and consequences of their illnesses. We are beginning to see cases in which almost no attention is paid to the specific kinds of interpersonal situations that have proven consistently overwhelming to patients, and no attempt has been made to identify the family, social, and vocational stresses that have immobilized patients and caused them to decompensate. The result is that little is done to help patients resolve these stresses, modify pathological patterns of behavior, and work with community resources.

Psychiatrists must become more involved in community mental health and should reassert their leadership. As the group of mental health professionals with both the broadest and most intense training in relevant areas, they have an unmatched overall perspective. Furthermore, the burden of ultimate responsibility for patient care that both law and tradition place on them makes any arrangement in which they serve simply as "team" members strained and cumbersome. They should not be deterred by accusations that they want to "perpetuate an outmoded medical model" or that they are "motivated by their power needs." Where there is truth in such indictments, they must be alert to it and correct their orientation and attitudes. Realistically, there is no other professional group that can adequately fill the gap if psychiatrists abdicate leadership; the result will be a chaotic battle with no rational means of settlement. We do not mean to imply that possession of an M.D. bestows administrative or social expertise or that nonmedical professionals have no leadership role. We simply assert that, in general, psychiatrists are better prepared for leadership than other professionals.

Finally, the training of psychiatric residents should be geared to meet the needs of the public and not the needs of a relatively small group of private psychotherapy patients. Residency programs should involve service to the needs of the total population (including the long-term severely mentally ill); training in crisis intervention; operation of a follow-up system for all patients; experience with rehabilitation, with resocialization programs, and with 24-hour care in graduated levels of intensity; and information and education programs for the public and professionals (17). The psychiatrists of tomorrow need to be oriented to the importance of making deinstitutionalization work as well as learning the techniques of treatment and rehabilitation that make this possible.

Freedom of Inquiry and Subjects' Rights: An Introduction

BY DAVID REISS, M.D.

The author introduces the Special Section papers to follow, pointing out that two new issues have attached themselves to the issue of the physical safety and civil dignity of human subjects. One new issue is an emphatically legal defense of the concept of subjects' rights; the other is the evolution of political characterizations and caricatures of many forms of research.

DURING THE LAST FEW YEARS we have become much more sensitive to the issue of the rights of human subjects in medical studies. In my view, this accomplishment arises partially from the civil rights movement of the 1950s and 1960s. That movement made us all more sensitive to the intricate network of overt and covert social processes that offend human dignity and constrain human freedom. I think that our understanding of the medical experiment as a human encounter can only be enriched by applying what we have learned from other areas in which the civil rights of individuals have been championed. Another reason for the increased sensitivity to the rights of human subjects is the fact that during the last decade a series of painful and mortifying examples of the abuse of human subjects by scientific investigators has come to light. This has led us to redouble our efforts to prevent the abuse of human beings in research.

The story has not ended here, however. Those of us who spend our days engaged in research on human beings are becoming aware of additional problems relating to the human nature of medical research. These problems were at first hard to detect. In the beginning, it seemed that they too arose from the intense and impassioned defense of the dignity of human subjects; we heard more strident and urgent demands for the protection of human subjects, demands with which we could only agree. As time went on, however, particularly in the last two to three years, we seem to have been dealing with something new. As I see it, two new issues have attached themselves to the issue of the physical safety and civil dignity of human subjects. This theme is treated in more detail in the papers to follow. I will mention them only briefly here.

The first additional issue is an emphatically legal defense of the concept of subjects' rights. An increasingly complex set of government regulations is being elaborated to protect the experimental subject. This is vastly increasing the administrative complexities of conducting research. More important, it is crystallizing and formalizing an adversary relationship between subject and researcher.

The second issue is perhaps more ominous. It is the evolution of political characterizations and caricatures of many forms of research. A number of highly vocal groups are conceptualizing some psychiatric research as a political process that by its very nature threatens human freedom. The most conspicuous object of attack is behavioral genetics; this line of research has been caricatured as based on a creed that harkens back to Nazi Germany and that threatens to provide a rationale for weeding degenerates out of the human community. Similar political concerns have been raised about other research areas, including behavior modification, narcotics addiction, and psychopharmacology.

Our concern is that current efforts to protect subjects' rights, intensified by legal and political tactics, are providing serious obstacles to the conduct of research. I wish to emphasize that this by itself is *not* grounds for dismay. If subjects have actually been abused and if heroic measures are necessary to protect them, then it may be legitimate to accept curtailment of some research. However, we cannot accept such a conclusion without careful and concerned review. Indeed, in my view, the present threat to some areas of psychiatric research is so real that another form of hu-

Presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Reiss is Professor, Department of Psychiatry and Behavioral Sciences, Center for Family Research, George Washington University School of Medicine, 2300 Eye St., N.W., Washington, D.C. 20037.

man freedom and dignity is severely threatened: our right to know and understand the forces that affect our lives; in short, the freedom of inquiry. Today we may be approaching a highly ironic, if not tragic, impasse where the freedom of inquiry comes into serious conflict with forces defending subjects' rights.

The first five papers in this Special Section of the *Journal* were presented in a session at the 1976 APA annual meeting. I chaired the session. The papers serve two functions. First, they survey the problem. They assess the obstacles that political and legal forces have erected against research and estimate the damage already done. Dr. David Musto, an eminent psychiatrist-historian, sets the matter in historical perspective; he notes the major forces that have arisen to support or retard laboratory research during the last few centuries. The focus of the papers then shifts to the severe problems in the present. Many sectors of psychiatric research are suffering and could have been selected for review; these sectors include behavior modification, behavioral genetics, and mental retardation. I chose three particular areas that have been hard hit to serve as examples of the growing emergency in psychiatric research. For each of the areas selected, I asked one of its most eminent and experienced investigators to review the current state of affairs. Dr. Jonathan Cole reviews problems in psychopharmacology, Dr. Roger Meyer reviews problems in narcotics addiction research, and Dr. Lee Robins reviews problems in follow-up studies. Drs. Cole and Robins focus on the intended and unintended destructive consequences of the newly constructed legal maze surrounding human subjects. Dr. Meyer comments on the disturbing problems arising from political opposition to research.

The second function served by these papers is to explore practical solutions for reconciling subjects' rights and the freedom of inquiry. The papers by Drs. Cole, Meyer, and Robins contain a number of practical suggestions; the paper by Dr. Bradford Gray focuses exclusively on the problem. Specifically, Dr. Gray focuses on research review committees (often called institutional review boards). These committees are now required by the U.S. Department of Health, Education, and Welfare in all institutions in which it funds research. The alert reader should not mistake these institutional review boards as just another harmless bureaucratic cog in the academic research machinery. They are a harbinger of a whole new process in psychiatric investigation as well as in other areas of biomedical research. They represent a systematized and powerful mechanism by which scientists and laymen can decide what research with human subjects may or may not be done. If this review process goes awry it can cause endless mischief and incalculable damage. If it functions properly, however, it bears the promise of reconciling subjects' rights and freedom of inquiry.

Taken as a whole, the papers in this Special Section are addressed to our colleagues in research and, more importantly, to our colleagues in teaching and practice. Beyond that they speak to legislators and to the general public, who are the beneficiaries of mental health research. I think we can all agree that a new age is dawning in psychiatry. During recent decades diligent and skillful practitioners have defined a set of major problems in psychiatric assessment, etiology, and treatment that require painstaking research of the highest caliber to solve. For their part, psychiatric researchers have developed exciting new theories and methods and have started to help solve some of these urgent problems. This productive cycle continues as practitioners and teachers, testing the new methods, have facilitated new advances in our field. This precious cycle of practice and research is one that we have hoped for and, as have other branches of medicine before us, seem finally to be achieving. Our concern is that this cycle may be severely interrupted just as it is becoming firmly established. Thus we ask the reader to examine the issues raised in these papers for their broad implications for psychiatry as a whole. We invite observations, comments, and suggestions.

Freedom of Inquiry and Subjects' Rights: Historical Perspective

BY DAVID F. MUSTO, M.D.

The author presents an historical overview of the various attitudes toward animal and human experimentation. He cites advocates (Bacon, Welch) and opponents (Johnson, Shaw) and traces the debate from the Graeco-Roman era, through the rise of the scientific establishment, to the present. Controversy over the fundamental rights of individual research subjects versus a future-oriented freedom of inquiry has been and continues to be a dilemma for clinicians and research scientists.

GEORGE BERNARD SHAW had a seemingly inconsistent scorn for what we would hail as some of the medical profession's finest achievements. He regarded bacteriology "as a superstition" and compulsory vaccination on the same level as compulsory baptism. His full fury, however, was aimed at the laboratory technique almost synonymous with Pasteur, Koch, and Sherrington: experiments on living vertebrates or, more broadly defined, vivisection. Shaw saw no sharp demarcation between animal and human experiments and no justification for either. In 1911 he argued that "the exemption of the pursuit of knowledge from the laws of honor is the most hideous conceivable enlargement of anarchy . . . a curious devil might destroy the whole race in torment, acquiring knowledge all the time from his highly interesting experiment" (1, p. 56). Shaw liked to enrage his enemies and astound everyone else, but this sentiment was no casual jab at medicine. More than one of Shaw's readers have wondered how such a self-advertised advanced thinker could be under the spell of an antiscientific sentimentality.

We find less puzzling the testimony in 1900 of Dr. William Henry Welch to a Senate committee considering an antivivisection bill. First Dean of the Johns Hopkins Medical School and a world-renowned bacteriologist, Dr. Welch spoke against restrictions such as Shaw would impose on the freedom of inquiry:

> Our own contributions to [medical] progress may now be small, but America is destined to take a place in this forward movement commensurate with her size and importance. We today should be recreant to our great trust, did we not do all in our power to protect our successors from the imposition of these trammels on freedom of research. Our appeal to you is not only in the name of science, but in the truest and widest sense in the name of humanity. (2, p. 101)

Backed by influential and educated Americans defending medical research, Welch won an overwhelming victory against the antivivisectionists. Shaw's crusade to stop animal experiments was no more successful than his campaign for a new English alphabet.

Today we are again questioning whether medical research on living beings should be severely restricted or perhaps even prohibited. I would like briefly to sketch some history of the strife so eloquently represented by Shaw and Welch and still divisive in 1977.

EARLY VIEWS ON RESEARCH AND PROGRESS

Human experimentation involving drugs, diet, regimen, and surgery has existed as long as one person has treated another, although institutional and methodical experimentation on humans was uncommon in the Graeco-Roman era. At the height of Athenian excellence scientific inquiry seemed merely a strange pursuit and gave Aristophanes' audiences a good laugh. His portrait of Socrates in *The Clouds* as headmaster of a school for pure research did not reveal Athenian fear of any tangible evil resulting from scientific research or, for that matter, recognition of any practicality. Interestingly, Aristophanes linked pure research to an atmosphere of sophistry and an attack on old values.

The Western classical world did not expect that scientific inquiry would bring radical and quick improvement in life-style, transportation, communication, and health and felt that only more of the traditional elements of the good life might be obtained through wealth, power, or luck. The rise of Christianity devalued even the material rewards wrought by temporal success: progress would be spiritual and measured externally by charitable actions. For both Christian and pagan, each believing the world in decline after a distant Golden Age, progress itself was an uncommon concept. Conflict between freedom of inquiry and subjects' rights required establishing experimental science

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Musto is Associate Professor of Psychiatry, Child Study Center, Yale University School of Medicine, 333 Cedar St., New Haven, Conn. 06510, and Associate Professor of History, Yale University Graduate School.

and medicine as social institutions. Until science could wield practical knowledge with a beneficial impact on everyday life, it would tend to yield when in conflict with ethical and cultural traditions.

Francis Bacon at the beginning of the 17th century held a larger vision of science. He minimized exaltation of truth for its own sake, feeling that science must be utilitarian. As Lord Chancellor, Bacon urged King James to support scientific academies and intensive experimentation into practical problems, but it was too early in the scientific revolution for Bacon's ideas to appeal much to practical minds. King James listened incredulously and then, with an Aristophanic wink, remarked that Bacon's ideas were "like the peace of God, which passeth all understanding."

RISE OF A SCIENTIFIC ESTABLISHMENT

Bacon's desire for a practical, experimental, scientific enterprise would be gratified later in the 17th century when experimenting became a fad for advanced thinkers, scientific minds, and practically anyone looking for a new hobby. Restoration playwrights ridiculed experiments of the Royal Society as much as any Attic comedian had mocked Socrates. Telescopes, microscopes, vacuum chambers, and timepieces became, depending on the observer's perspective, tools or toys for the curious. Squints at fleas and microorganisms could amuse or instruct, but crude operations on birds, cats, dogs, and horses disgusted some observers and experimenters. The pain apparently felt by animals was one criticism, but the effect of experimentation on the investigator's virtue was as often invoked against the practice. One is reminded of Thomas Jefferson's warning that the most damaging effects of slavery were on the slave-owner's character.

Bacon's contemporary, William Shakespeare, portrayed this negative aspect of medical research in *The Tragedy of Cymbeline* (c. 1610). A malicious Queen eager to investigate the "most poisonous compounds" applies to a court physician offering what must be one of the earliest research protocols:

> . . . I will try the forces
> Of these thy compounds on such creatures as
> We count not worth the hanging—but none human—
> To try the vigor of them, and apply
> Allayments to their act; and so by them gather
> Their several virtues and effects.

The physician, moral more than curious, warns her that this research will harden her heart, and then confides to the audience:

> I do know her spirit
> And will not trust one of her malice with
> A drug of such damn'd nature. . . .
> . . . first, perchance, she'll prove on cats and dogs,
> Then afterward up higher. . . .
>
> Act I, scene v

To those shocked by a vogue for animal experimentation the question recurred, Does curiosity require cruelty for satisfaction? The carefully timed drowning of animals, cutting living dogs open to study respiration, and asphyxiating kittens in a bell-jar evacuated of air could have such specific and important scientific goals as learning whether the lungs needed ventilation in order to support life. As for allegations of cruelty to animals, even troubled researchers could reply that the Bible had given man mastery over animals. In these investigators' own time Descartes submitted that because only man had a soul, only man could feel pain; an animal could be damaged, but not hurt.

Questions persisted into the 18th century over the morality of animal experiments. Dr. Samuel Johnson, an ardent antivivisectionist, complained bitterly that in animal experiments "knowledge is not always sought, and is very seldom attained." Like Shakespeare, Johnson saw experimentation hardening the heart of the experimenter, extinguishing "those sensations which give man confidence in man, and make the physician more dreadful than the gout or stone" (3, p. 56).

What would Dr. Johnson say in 1850 or 1900? Could discoveries in bacteriology, immunology, surgery, and pharmacology have been made without animal experiments? What would be Johnson's reaction to the possibility that our generation may see the last case of smallpox? All modern societies willingly offer influence and prestige to medical researchers for the practical benefits they provide. The power given research, however, has created a deeply felt dilemma over the rights of individual research subjects. Is it simply a tough law of nature, as one defender of human experimentation stated in 1882 (4), that "the few must suffer for the many"? Dramatization of contemporary research would require Euripides, not Aristophanes. We have descended from Cloud-cuckoo land to the cancer ward.

FEAR OF AN UNCHECKED SCIENTIFIC ESTABLISHMENT

Two kinds of fear about science coexist. On a mass scale, there is the Frankenstein spectre that science will learn through experimentation some destructive secret. We already confront an atomic bomb; could we also acquire an epidemic of an untreatable, fatal disease as a result of genetic manipulation with viruses?

Shaw and Dr. Johnson did not address the catastrophic possibilities of science's freedom of inquiry; they feared small-scale effects as this imperial institution came into contact with one person, then another, and another—isolated individuals before a juggernaut. This is the other fear underlying current efforts to safeguard subjects' rights. Johnson worried about the experimenter who becomes a cog in the juggernaut's wheel when he regretted, "he surely buys knowledge dear, who learns the use of lacteals at the expense of his humanity" (3). Shaw was outraged on behalf of the

promptly jailed "conscientious objector" to vaccination.

The antivivisectionists believed experiments on living beings destroyed sensitivity to charitable relations between people and between people and animals. Was the new world promised by science worth sacrificing a fragile and precious form of moral development? Understandably attracted to this zealous movement were protagonists of other struggles who shared resentment toward repressive and indifferent social institutions. Women fighting for equal rights and angry defenders of deprived social classes, who suspected physicians used poor patients as human guinea pigs, combined to protest against the depersonalizing trends of industrial and scientific progress.

By the 1870s animal experiments began providing practical, at times almost miraculous, medical advances. As a series of remarkable discoveries quickly increased chances for a healthy and comfortable life, the public naturally assigned great responsibility for these startling advances to animal experiments. Antivivisectionists could not compete with the enormous hopes held for future medical research. Support for all kinds of scientific research has built a gigantic social institution. The result is that most of the scientists who ever existed are alive today, and they create an unparalleled demand for human research subjects. The consequent routinizing of human research on a grand scale may be related to Professor Bernard Barber's claim that human experimentation of questionable ethics reaches its highest percentage in run-of-the-mill "mass producers" of scientific papers (5).

COUNTERFORCES TO THE SCIENTIFIC ESTABLISHMENT

If we compare present criticism of research on humans with the heyday of antivivisection activity in the last century, we find similar pressures against experimentation and in favor of strict, perhaps prohibitive, safeguards for subjects' rights. In the 1870s a sizable minority could still question whether the spiritual costs of vivisection—including human experimentation—were balanced by hope of practical benefits. Now, having gained dramatic victories over childhood and infectious diseases, facing apparently slow progress on diseases of later life, and suspecting an excessive busy-work quest for human research subjects, critics argue that many experiments on humans could be reasonably eliminated. Perhaps we have reached, on a higher plateau of practical knowledge, a new equilibrium of lowered expectations from science and its research methods. This new balance may be found in demands that now is the time to consolidate what we already possess in scientific advances, distribute health services more equably, and develop sensitive ethical relations with one another. The spirit of conservation, so prominent in the environmental movement, has weakened a once simple faith in the benefits of untrammeled research by emphasizing the dangers of new (and old) technology to the quality of life. Further, some disadvantaged groups find the complex technology of experimental scientists repressive rather than evidence of a mysterious power over illness; they feel it excludes them from a higher social status while they are being used as subjects to sustain the scientists' prestige. Contemporary echoes can be heard in the warning, over 80 years ago, of an English antivivisectionist and opponent to medical research on humans:

> In its relation to science and her operations, the working class occupies, and is beginning slowly but surely to realize that it occupies, a position perilously more near to that of the vivisector's subject than to that of the patient of the fashionable physician. . . . And whatever gains may be achieved by the process will be achieved, not for its benefit, but at its expense.(6)

COMMENT

A similarity worth consideration between current opposition to experimental procedures and earlier strenuous opposition to vivisection is a turn among some thoughtful people toward a primary emphasis on the style or quality of each individual's life. For them, justifying risks today to obtain possible future scientific miracles has become less attractive, and unrestricted human experimentation has become an unnecessary hazard. Critics will point out that this emphasis on "quality of life" is possible because the scientific achievements of the last two centuries have created a relatively satisfactory quality. Isn't the internal meaning of life easier to contemplate when external risks are less threatening? Or is the declining enthusiasm for medical research a valid reawareness of our common mortality, which has been obscured by a century of unique, but still inevitably limited, medical progress?

The skeptical attitude toward research on humans so confounding to investigators may announce resurgence of modest expectations from utilitarian science, an attitude of near indifference mankind found congenial and proper until, historically speaking, quite recently. Those questioning the wisdom of seeking unlimited material progress must be sympathetically understood if an accommodation is to be made between future-oriented freedom of inquiry and our here-and-now rights as living beings.

Research Barriers in Psychopharmacology

BY JONATHAN O. COLE, M.D.

The author discusses barriers to psychopharmacological research, including attacks by vocal human rights groups, regulation by local review boards, and Department of Health, Education, and Welfare restrictions. He suggests that those patients least able to give informed consent are most in need of the benefits of research on new drugs.

OUR CURRENT ARRAY of drug therapies for psychiatric patients is often helpful but is inadequate for the needs of many patients. Antipsychotic drugs improve the conditions of only two-thirds of schizophrenic patients treated with them. Even patients who improve often continue to be socially ineffective and to suffer from delusions, hallucinations, and thought disorder. In addition, some drugs have undesirable early and long-term side effects. Antidepressants, for example, take one to three weeks to act, have anticholinergic and cardiovascular side effects, and improve, at best, one-half of the patients treated. The most effective antianxiety drugs can cause psychological and physical dependence. Drugs used to treat senile dementia are either ineffective or can be distinguished from placebo only with difficulty. Mental retardation and severe personality disorders lack drug therapies almost entirely. Current drugs are a vast improvement over the electroconvulsive therapy, insulin coma therapy, and barbiturate sedation that were the only treatments available in 1950, but many patients are still chronically distressed, dysphoric, and nonfunctional, despite our best efforts at drug therapy and psychosocial therapies.

It seems to me that public policy over the last few years has been making the development of better drug therapies in psychiatry more and more difficult. Well-meaning regulations have caused the costs of drug development at the preclinical level to sky-rocket and, at the clinical level, have placed a growing array of bureaucratic hurdles between the investigator, the patient, and the acquisition of new knowledge. Regulatory agencies and treatment facilities are getting deeper in red tape, much of which is alleged to be in the interest of patients' rights and safety. Pressure for these escalating rigidities seems to come, however, from a small group of very vocal laymen who are hypersensitive to a range of risks—e.g., to privacy, safety, humanity—but seem totally uninterested in the benefits of better therapies. As one reads attacks on clinical drug research, one gets the feeling that the attackers believe that mental illness and suffering do not exist and that all mental patients would be better off totally untreated or that a little love and moral support can make everyone happy.

It is ironic that at the same time there is public pressure to prove that drug therapies are really effective, something which cannot be done without controlled clinical drug studies. Current restrictions make studies of drug therapies very difficult and make more basic studies that use drugs as tools to study the biological bases of psychiatric disease even more difficult.

PRESSURES TO STOP ALL RESEARCH

Recent attacks on psychiatric drug research by small groups of enraged citizens have caused some public mental hospitals to abandon all drug research. The attack on the Missouri Institute of Psychiatry by the Scientologists is one alarming example; the attack

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Cole is Director of Clinical Research, Institute of Research and Rehabilitation, Boston State Hospital, Boston, Mass. 02124, and Chief of the Psychopharmacology Program, McLean Hospital, Belmont, Mass.

by a legal aid group on research at the Lafayette Clinic in Detroit is a second. The killing of a controlled study of drug therapies for disturbed children in Boston is a third instance. In all of the above cases the research attacked was dropped even though it had met all Department of Health, Education, and Welfare (DHEW) and local institutional requirements. A study of a narcotic antagonist using paroled drug addicts in Boston was stopped in the same way.

Research in a number of prison systems—most recently in the Federal Bureau of Prisons—has been stopped by fiat in the past couple of years. Research in public mental hospitals may well be the next to go. Although one can argue the pros and cons of drug research with prisoners (I personally believe that prisoners can give informed consent, that payment for their trouble is legitimate, and that they can in this way partially repay a real debt to society), the actions on the part of prison administrators, at least in Massachusetts, have been in response to pressures from vocal minorities; it's easier to stop all research than to be hassled by angry groups. The social need for research and the rights of the many prisoners who want to participate in research have not, I believe, been considered at all seriously.

Although the overall threat to psychiatric drug research is ominous, in many settings it is only a cloud visible on a distant horizon. The current DHEW regulations, however, are a real, present, and pervasive difficulty.

THE REVIEW GROUP

Present regulations require an institutional review board (IRB), which must have totally disinterested (but unpaid) citizen members. This latter requirement sounds reasonable but presents grave practical difficulties. How can one find mature, sensible citizens who are willing to put in a lot of time without pay to review and monitor studies? At one of the two institutions at which I do research all such members come for two or three meetings and then gradually disappear, despite our best efforts to retain them. When present, they are usually helpful and reasonable.

Such committees, like all committees, can get incredibly hung up over minutiae. For example, one IRB spent five hours of time over several weeks considering the problem posed by offering schizophrenic patients in an aftercare program $20 to participate in two two-hour sessions of electroencephalographic recording. After the issue of too much versus too little pay had been beaten to death, the possibility that patients in marginal job situations might jeopardize their jobs by volunteering for the study was brought up. The issue of harm from research versus individual rights of self-determination was argued vigorously and interminably. To make matters worse, it was never clear that any of the available patients actually had jobs to begin with. What I am trying to say is that committees can become embroiled in personality conflicts and can reflect institutional schisms; these problems can lead to agonizing deliberations that are generally irrelevant to issues of human safety or patients' rights. All bureaucratic remedies are likely to have undesired and sometimes unanticipated side effects.

In addition, with the current review process required by the National Institutes of Health (NIH) and the Alcohol, Drug Abuse, and Mental Health Administration, investigators face double jeopardy. A research design acceptable to a local IRB may be vetoed at the NIH level. All multilayer systems of this sort increase the likelihood that someone will say "no." Nowhere in current regulations is there any provision for appeal of a restrictive ruling made at any level to a review group at a higher level. I'm not even sure I want an appeal mechanism—it would tie up even more time and create more paper work; however, the more elaborate our safety review systems get, the less progress will be made in clinical research.

INFORMED CONSENT

A larger and more unique barrier to psychiatric drug research is the requirement that full, informed consent be obtained in writing from all patients. At one level, I doubt that most nonpsychiatric medical patients are capable of really understanding all the issues and risks involved in consenting to participate in either drug studies or conventional therapies. The risks in most drug studies are less than those associated with elective surgery or even with receiving penicillin for a streptococcal infection. Patients asked to participate in drug studies have a lot more freedom of choice than do patients who go to their own doctor for routine treatment. In neither case can one ever be sure that full information is imparted and understood.

A more serious problem for psychiatric research is that the patients needing better drug therapies the most—treatment-resistant chronic schizophrenics, patients with senile dementia, mental retardation, or marked behavioral disturbance—are often the least able to give informed consent at all. The appointment of legal guardians for such patients is expensive and time consuming. It resolves the legal issue but may not resolve the ethical one. To deny such patients any research drugs may leave their rights intact but will also deprive both the individual patient and such patients as a class of any chance to benefit from new therapies. At worst, it leaves them treated with older therapies which themselves have been inadequately studied in such patients.

It seems to me that degrees of risk exist and that degrees of consent should also be recognized. I find it hard to believe, for example, that a new technique for monitoring an old drug therapy—drawing blood to determine drug blood levels—requires any more "consent" than drawing blood to monitor diphenylhydantoin or lithium levels, providing such a proce-

dure is done only occasionally. The physical risk is nonexistent, the discomfort is slight. In cases in which the patient's privacy might be violated—a very unlikely event—the IRB could handle this problem without escalating the whole issue to the signed-consent level. If a series of blood samples or a venous catheter is required, informed consent is desirable but should not be mandatory.

With studies involving several blood drawings, several hours of polygraphy or EEG recording, or participation in psychological testing, it seems to me that the patient's willingness to participate (acquiescence) should be sufficient "consent." Most of these research procedures can't be done with resistive or uncooperative patients anyway. The patient's willingness to go along with the procedure—as he might with a clinically indicated EEG or psychological testing—seems to me adequate consent. Blowing up benign procedures into major issues seems unwarranted. Of course, the patient should be told about the procedure and its purpose and any attendant minor discomforts, but patients who are so impaired that it is unlikely they will fully understand the procedure should still be available for study without court-appointed guardians being required. The IRB should approve the study, including its provisions for protecting privacy and the manner in which cooperation is elicited.

Comparisons of standard marketed drugs used for an FDA-approved purpose also entail no greater risk than nonresearch treatment; use of patients unable to give full informed consent should also be possible in these studies.

I would also like to see a mechanism developed which would permit the study of very benign drugs of dubious clinical value in comparison with placebo in conditions for which no established treatments exist. Some of our current geriatric drugs (Hydergine, papaverine) would qualify for study under such a procedure, as might studies of established antipsychotic drugs in mentally retarded patients. In such cases consent from the next of kin might be the appropriate level of consent.

Obviously, either full informed consent or consent by a court-appointed guardian would be necessary for studies with new drugs or for procedures with greater potential risks. At even higher risk levels—where the potential for benefit is equally high or higher—special monitoring of consent procedures and of the patient's progress during the study may be desirable. I believe that acceptance of a range of degrees of acquiescence or consent appropriate to the risk or lack thereof is needed. Without this flexibility, minor research procedures become encumbered with complex mandatory procedures that were designed with psychosurgery in mind.

CONCLUSIONS

In my own limited experience, the "informed consent" issue has interfered with research in several ways. A study of cyproheptadine (Periactin), a marketed antihistamine, would have been carried out in chronic psychotic patients with tardive dyskinesia at Boston State Hospital if patients unable to give informed consent could have been asked to consent to take the pills. I believe that the risk would have been minuscule; a pilot study in a private-practice setting had been favorable. A study of the dose management of loxapine, a marketed antipsychotic, in agitated patients with senile dementia will probably not be done at McLean Hospital because informed consent by the patient or a legal guardian is required by our IRB. I am sure that this drug is being used unsystematically in such patients without the care involved in a careful clinical trial. A study of chlorpromazine blood levels in newly hospitalized schizophrenics has been greatly retarded by the requirement of prior informed consent; obtaining acquiescence for blood sample drawing during the early days of hospitalization and informed consent for use of the data later, when the patient had improved, would have tripled the rate at which the study was done.

It is interesting to note that the original purpose of informed consent was to protect the investigator from future tort actions; this role has been declared improper, and the procedure now serves a growing range of regulatory and bureaucratic purposes.

Barriers to research are being erected by pressure groups and regulatory agencies. They impede or threaten to destroy all research, but are particularly difficult in the area of clinical psychopharmacology. We are in real danger of preventing the development of any new drug therapies for mental illness unless more flexible procedures are developed. Many, many patients will suffer needlessly if we are compelled to continue to use only our current drug therapies for the next 20 years.

Subjects' Rights, Freedom of Inquiry, and the Future of Research in the Addictions

BY ROGER E. MEYER, M.D.

Since the recent passage of regulations concerning subjects' rights and freedom of inquiry, opposition by the public and others to some areas of research in the addictions has prevented its implementation or continuation. Research investigators in the biomedical and behavioral sciences have been placed in the position of defending their work in an adversary climate. The author points out the importance of transmitting to the public, the scientific community, and legislators the investigators' concern that "subjects' rights" not be viewed only in a legalistic context, but also in the context of not harming the patient.

TO THOSE OF US with a humanistic orientation who were educated in the medical schools of the late 1950s and early 1960s, the movement to apply human studies reviews and an ethical brake on research is understandable and justified. To those of us with a concern about the advancement of knowledge and the importance of free inquiry to our profession and our society, the present rush by some to condemn and restrict clinical research (and other scientific studies with human subjects) suggests a dangerous trend that may have moved beyond its initial noble impulse. The scientific community has responded by defending the enterprise on the basis of previous achievements and the continuing need for the struggle against diseases that afflict humankind. The failure of this defense was suggested by a recent editorial in the *New York Times* (1) equating this position with the defense mustered by our intelligence agencies on behalf of practices that were said to serve the interests of national security. In this context, our political system has seemed to be moving to set up countervailing forces and adversary procedures designed to "equalize" the interaction between research scientists and research subjects.

Presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

At the time this work was done, Dr. Meyer was Associate Professor of Psychiatry, Harvard Medical School, Boston, Mass.; Director, Harvard-Boston University Center for Biobehavioral Studies in the Addictions, Boston, Mass.; and Associate Director, Alcohol and Drug Abuse Research Center, McLean Hospital, Belmont, Mass. He is now Chairman and Professor, Department of Psychiatry, University of Connecticut School of Medicine, Farmington, Conn. 06032.

If the concern about research with human subjects were limited to a concern about inadvertent or unavoidable harmful consequences of innovative procedures or research methods, then one could realistically restrict potentially harmful procedures while providing a mechanism to compensate subjects who have participated in research and who have sustained inadvertent complications consequent to their participation in the experiment. This would be consistent with the medical ethic *primum non nocere*, "above all do no harm." We have, however, moved into an area where the ethics of human experimentation are increasingly being defined on the basis of "imperatives" that are more consistent with the principles, practices, and beliefs of civil liberties attorneys. It is in the context of these ethical imperatives that individual research investigators have been unable to defend their work and approved research projects have been stopped. To some, this situation is reminiscent of the legitimate anguish of the oppressed against the oppressor elite. To others, the situation is but one more repetition of the classic struggle between scientists and those who hold political power as to whether science shall serve or be independent of political ideology.

The distinguished philosopher Charles Frankel has observed that it is not technology per se that threatens mankind or a humanistic view of man; rather, the real threat lies in the tendency of some people to superficially link technological data to support for ideologies and movements (2). Indeed, on the issue of censorship of biomedical research, Frankel wrote,

> For while technology is equivocal in its consequences, one thing is not—the damage that ensues, almost always very quickly when a field of inquiry is banned because it is said to conflict with higher moral laws. The number of subjects that can come under this axe is indefinitely large. The character of the people who have ever wielded this axe is not reassuring. (2)

The future of clinical research seems least secure in areas of experimentation into the causes and treatment of nonlethal conditions, particularly in fields where treatment and prevention programs are polarized and scientific advances "appear" to offer little and may threaten philosophical positions. By these criteria, research into the causes and treatment of substance abuse should be controversial, and it is. There are two general areas of controversy that can be highlighted by

case examples. A third general area (confidentiality and privacy) has been described by Robins (3).

FREEDOM OF INQUIRY VERSUS RESTRICTED INQUIRY

The Study of Alcoholic Mothers

Data from a study by Jones and associates (4) suggest that offspring of alcoholic mothers may have a greater likelihood of premature birth and various levels of neonatal distress. The neonatal opiate withdrawal syndrome in the offspring of heroin-addicted mothers was described a number of years ago and has been updated by the work of Finnegan and associates (5). The question of neonatal distress in the offspring of alcoholic mothers is in need of more careful delineation.

A team of psychiatrists, obstetricians, and pediatricians at a municipal hospital undertook a study of neonatal behavior and development in the offspring of mothers who were being seen in the prenatal clinic and who were identified as having problems of alcohol abuse. The physicians offered a program of psychotherapy coordinated with the prenatal care to assist the expectant mothers with their drinking problems. Preliminary data suggested that the offspring of mothers who drank heavily were at high risk as compared with the offspring of patients who drank moderately or rarely. On the basis of these preliminary findings, a grant was prepared and submitted to the National Institute on Alcoholism and Alcohol Abuse (NIAAA). Because the protocol also included the support of a treatment and prevention program, the review group included persons who could consider all aspects of the study. One of the reviewers was a community activist on the staff of an agency affiliated with the medical school at which the work was to be done. Despite the fact that this institutional affiliation should have excluded him from the review, he participated in the review of the grant application and a subsequent site visit.

The NIAAA staff then demanded that, in addition to the already obtained institutional reviews, the protocol be considered by a locally constituted group called the Community Research Review Committee. After reviewing the protocol, the committee felt that the research might draw defamatory conclusions regarding the competency of black mothers, since 55% of the clinic population was black. The committee insisted on monitoring the personnel practices and conduct of the research and previewing any formal or informal reports emanating from the project. In order to effectively monitor the work, the committee members stated that they would have to receive a portion of the budget as overhead. The principal investigator was told that since it was already the responsibility of the NIAAA and the institution to monitor the project, federal funding for a third group of monitors could not be budgeted. While it was clear that the NIAAA staff had erred in requiring that the research investigator obtain the sanction of this locally constituted group, it was also clear to the research investigator that the full-scale program was not possible in the face of determined political opposition.

Narcotic Antagonist Project 1

The Community Research Review Committee has made similar budgetary demands upon a number of other nonpolitical research investigators whose research projects involved studies into the causes and treatment of nonlethal conditions. The committee members have been relatively selective in their approach and apparently have not made these demands upon all research investigators in the geographical area. On one previous occasion they approached a team of research investigators who proposed to study the effects of narcotic blocking drugs in a population of heroin addicts at the same municipal hospital. Their demands at that time included 10% of the budget, 50% of the positions, and the appointment of an associate director of the project from among the membership of their committee. They also demanded censorship of reports.

The thrust of the committee's concern regarding studies of narcotic antagonist treatment of heroin addicts seemed to be that the research investigators were taking a simplistic, biomedical view of a complicated social problem that (in its view) really required a solution to the problems of poverty and other social ills in the community. While the causes of addiction may be multifactorial, the committee was concerned that the biomedical orientation of the research project conflicted with its own view regarding the causes of the problem and its own definition of funding priorities. Faced with powerful opposition that undermined the support by the hospital's trustees, the research investigators chose to transfer this project to another community.

While individual communities will continue to be able to exercise a political veto over research within their midst, the real question concerns the application of this principle on a larger scale. At least one monograph prepared for the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (6) proposed to sanction "community consent," which it defined as "informed consent negotiated with the community in which it is planned to conduct research or from which it is planned to draw prospective subjects." If this recommendation is adopted in this form, its consequences for the future of research could be extremely restrictive. As the Edelin trial has demonstrated, such political pressure can come from diverse sources and can scapegoat ethical practitioners and scientists.

Federal Opposition to Behavioral Research

Political concern about behavioral research with relevance to addictive drugs has not been limited to ad hoc community groups. Comments by Senator Proxmire and the threat by several congressmen to cut off

funds from the National Institute on Drug Abuse prevented the implementation of an approved and funded research project at Southern Illinois University on the effects of marijuana on human sexuality. The researcher had previously obtained local lay approval for his study, in addition to required institutional reviews.

The penultimate federal document challenging the ethics of behavioral experimentation was a report prepared by the Senate Judiciary Committee on Individual Rights and the Federal Role in Behavioral Modification (7). The report alleged,

> The behavioral technology being developed in the United States touches upon the most basic sources of individuality, and the core of personal freedom. . . . While psychosurgery under certain forms of electrophysiology is perhaps the most . . . sophisticated method of behavioral control, there are now being tested a number of other techniques based on more traditional, psychological principles [that] pose similar questions with regard to individual liberties. (7)

The implications of this report suggest the need to restrict behavioral research in the interests of the civil rights of individuals in the future, as well as the present. It is curious that alcoholism and drug addiction are major behavioral disorders whose alteration will require one or another form of behavioral modification. Indeed, methadone maintenance, narcotic antagonist treatment, and self-help residential programs all seek to modify behavior. The issue would seem to be whether clinical research in these areas can proceed in a variety of voluntary and nonvoluntary settings with appropriate regard for adequate and voluntary informed consent.

SUBJECTS' RIGHTS VERSUS THE RIGHT TO TREATMENT; SUBJECTS' RIGHTS VERSUS SOCIETY'S NEEDS

There is a recurring notion that research subjects must be protected from researchers by an adversary process (consent committees versus review committees, and patient advocates versus research physicians). The adversary process is a legal construct that works effectively in the courts and the political system. When applied outside this framework to the practice of medicine and research, it may run counter to the medical ethic of "do no harm." Indeed, as in the field of mental health generally, the arbitrary imposition of "individual rights" in a legal context may impose medical and social risks for individual patients. The following examples highlight the problem in addiction research.

Narcotic Antagonist Project 2

Vaillant (8) has carried out extensive follow-up studies on heroin addicts discharged from the U.S. Public Health Service Hospital in Lexington, Ky. From his work it is clear that patients who are on probation or parole do better in all forms of treatment. Indeed, many of the self-help residential "concept houses" have increasingly restricted admission to patients who are court referred because the dropout rate of volunteers in these hierarchical, authoritarian environments was too high. Vaillant's findings are clear: in the absence of some system of control, the addict is not able to modify his own behavior. As I have described elsewhere (9), that control can be manifested by methadone maintenance; an authoritarian, hierarchical residential community; or the criminal justice system.

The recidivism rate of former heroin addicts discharged from prison is quite high. This population presents unique problems in terms of the relatively effective treatments available to narcotics users. Since they have been drug free for a period of time in prison, they are not considered appropriate candidates for a program of opiate substitution (e.g., methadone maintenance). Since they have been living in a prison for a period of time, they are not anxious to volunteer for a 9- to 24-month residence in a "concept house." While parole or probation support may be helpful to the individual in his efforts to seek a job or obtain some sort of counseling, the presence of many stimuli associated with previous addiction cycles (familiar friends and "drug copping areas") may encourage relapse. The National Institute on Drug Abuse recognized that this population might be ideal for narcotic antagonist treatment. They funded one such project in one community in association with that city's drug treatment program. The principal investigator of the project described its course as follows:

> The project as approved and funded by HEW proposed to offer treatment to prison inmates shortly prior to their release from prison and during a parole period subsequent to release. A condition of the project . . . stated that under no circumstances could participation in the project be a consideration for parole. Plans were finalized for the conduct of the project in such a way that patients would not be approached to give informed consent until after the parole board had met and voted for parole. Despite the fact that a joint medical school and hospital based human studies committee approved of this project, the study attracted widespread local attention when the research protocol was stolen in a burglary of the office of the principal investigator. [The study was described in the local media in such a way that prison inmates were seen as guinea pigs and parole was described as dependent on participation in the study.] As a consequence of the widespread circulation of these allegations, community based and other agencies' human study committees requested review of the project. In a long series of reviews, multiple meetings resulted with four additional human studies committees, and the project met with final approval shortly before the expiration of the project period. Only two subjects entered the research study and HEW finally made the judgment that extension of the project with refunding was unwise. The principal investigators viewed the episode as

one of continuous harassment by an ill-informed media and a series of well-intentioned but unsophisticated and at times ad hoc human studies committees.

When one considers the number of "rehabilitation measures" that are routinely employed in the context of parole, probation, and other aspects of the criminal justice system, one is struck by the fact that these measures are seldom evaluated. Indeed, if informed consent is ruled out for this population in an a priori manner, then the population will be exposed to all sorts of unevaluated interactions with undefined risks while being prevented from participating in rehabilitation programs with a research-oriented design.

The Addiction Research Center

Forty years ago the Public Health Service set up the Addiction Research Center at Lexington, Ky., in order to screen new drugs for their potential to cause addiction, to explore the biomedical and behavioral aspects of the addiction process, and to evaluate potentially promising pharmacological approaches to the treatment of addiction. Over the years the mission has evolved consistent with evolving federal priorities. The addiction liability of many new analgesics became known before they could be advertised as "nonaddicting." The human pharmacology of methadone, *l*-α-acetylmethadol, cyclazocine, naloxone, and naltrexone were all delineated at Lexington. Over its 40-year history there have been no deaths or serious disabilities consequent to this research. With the development of locally constituted drug treatment programs in nearly all parts of the country, the need for a "treatment farm" for volunteers in Kentucky became unnecessary. Instead, in 1973 the Federal Bureau of Prisons relocated its facilities for known heroin addicts to Lexington in proximity to the Addiction Research Center.

It is now four years later. The staff at the Addiction Research Center was told that they could not begin any new studies using federal prisoners after January 1, 1977. The distinguished team of pharmacologists and behavioral scientists has been perplexed. Dr. William Martin testified before the National Commission for the Protection of Human Subjects in March 1976 concerning the importance of the work and the safety of the procedures. Within a month of Dr. Martin's testimony, the Bureau of Prisons acted independently in response to congressional inquiry and unilaterally ordered the end of research in prisons under its jurisdiction. This order came out before the conclusion of deliberations and the preparation of the final report by the national commission. In his testimony, Dr. Martin wondered how society's needs for safe analgesics and new pharmacological approaches to the treatment of addiction could be reconciled with the closing of Lexington. He reviewed the safety of the procedures at Lexington, and he argued that the prisoners were capable of giving informed consent.

COMMENT

Four issues have been raised with regard to informed consent in research involving the mentally disabled, children, and prisoners: 1) the question of the capacity of individuals in each group to give informed consent, 2) the question of coercion, 3) the question of a need for an adversary procedure to defend the rights of research subjects, and 4) the question of community consent. While all four of these questions have been applied to the mentally disabled, only one has been applied to research with prisoners and persons in the criminal justice system—the issue of coercion within an institutional setting. Persons living within institutions are thought to be at risk for coercion. One of the monographs prepared for the commission, which dealt with the mentally disabled, stated, "When proposed research is considered therapeutic, an institutionalized individual may be under more pressure to participate insofar as the possibility exists that the anticipated benefit may relieve the mental illness, and thus increase the likelihood that the patient would be released" (10). So far as research with prisoners is concerned, the problem of coercion has been presumed to exist in all phases of the criminal justice system.

Regarding research with drug-dependent patients, there may be the presumption of mental disability, and all four issues of informed consent have been raised in different contexts. There has been a tendency in some quarters to assume that diminished capacity exists, that coercion by the researcher is likely, and that adversary procedures and some form of community consent are essential to protect the individual rights of research subjects.

The resolution of these issues will be different if primary concern is given to the health and safety of the individual and society's needs as opposed to individual rights. It is paradoxical that the case for "health and safety," "society's needs," and "individual rights" is usually argued for hypothetical individual patients and subjects by elitists who presume to know more than the patients themselves about what is "good" for them. Indeed, the struggle between objectivism, intellectualism, and the pursuit of knowledge on the one hand, and subjectivism, anti-intellectualism, and equality[1] on the other, is a political conflict with implications beyond the limits of biomedical and behavioral research. Daniel Patrick Moynihan has quoted the political philosopher Joseph Schumpeter in words that seem to have some relevance: "It is an error to believe that political attack arises primarily from grievance and that it can be turned by justification. Political criticisms cannot be met effectively by rational argument" (11).

[1] "Equality" has recently come to mean that all points of view are equally valid in any situation involving two or more persons, that the power to veto is distributed widely and across many issues, and that executive power (literally the power to execute, implement, or develop) must be reduced until progress proceeds only by consensus.

In the present climate, appeals to the need for scientific advancement will not, and are not, convincing those with power and authority to let the enterprise continue in a number of communities. The research projects that have been stopped were defended (it seems to me) in a characteristic way. The research investigators met repeatedly with their most militant adversaries. They did so at the urging of their colleagues, who let them enter these meetings without significant support. The principal investigators and their colleagues believed that reason would prevail and that they would be able to convince their most ardent opponents. At the least, they expected that they could effect a compromise that would enable them to continue to work and would enable their adversaries to feel that they, too, had accomplished their ends. The institutions that had previously supported the research now supported the mediative process, thereby invalidating the previous support of the project that had been granted by the human studies committee and other relevant structures. Committees were set up to assist in the mediation; the committees usually consisted of the more militant opponents of the research and some individuals who were deemed friendly (although not emotionally committed) to the work of the research investigators.

It is untenable for the research investigator to defend his work on his own. It is also probably untenable for the scientific community to defend itself without major support from lay organizations. Previously, lay groups, like some of their scientific counterparts, have been organized to support categorical research. This has increased the risk of "salami tactics" by opponents of research, since attacks on individual projects have not been considered a threat to broader categories of biomedical and behavioral research. A coalition of lay persons and biomedical and behavioral scientists may be essential at this juncture to present to the public, the scientific community, and legislators a concern that includes freedom of inquiry *and* subjects' rights. Subjects' rights should not be stated only in a legalistic context, but also in the traditional context of "do no harm." Scientists have a major educative role relative to the public and the surface has barely been scratched. The adversaries of science are doing much better.

Problems in Follow-Up Studies

BY LEE N. ROBINS, PH.D.

Recent regulations concerning consent procedures and protection of privacy fall most severely on follow-up studies of children. Indeed, rigorous sample selection, nearly complete follow-up, and objective assessment of outcome are virtually impossible now. Further, compliance *with current "subjects' rights" regulations sometimes seems potentially more harmful to the subjects than is the research itself.*

RECENT REGULATIONS by the Department of Health, Education, and Welfare severely limit direct access to certain groups as research subjects (i.e., prisoners, children, and the mentally disabled). At the same time, new laws passed to protect privacy make indirect access by review of records virtually impossible for the researcher. These two changes have created a situation in which the ability to use follow-up studies as a research tool for understanding the causes and consequences of psychopathology and childhood deviance and to evaluate the effectiveness of the prevention and treatment of these problems has been seriously compromised. Indeed, most of the research tools I have used in the past 15 years to locate and evaluate the long-term outcome of child patients and normal control children have now been declared off limits to the researcher. I would like to argue that the researcher's access to a variety of records is necessary and not excessively dangerous—indeed, a good deal less dangerous to research subjects than is compliance with the new regulations.

The techniques that I have used and have encouraged other researchers to use are generally considered a good way to produce unbiased results in the very difficult area of separating the causes of deviant behavior and psychopathology from their effects. In simplest outline, to study factors in the risk of developing psychiatric disorder, the researcher chooses a general or high-risk sample from a population roster established before the age of risk for onset of the problems to be studied. He uses records or case histories dating from that early period to establish levels of familial, social, and behavioral variables that may influence the occurrence of the problem. He then follows the sample subjects after they have been at risk for the problem and evaluates their outcome by interview and record research. This method allows the researcher to 1) locate almost all of the subjects for follow-up, 2) test the importance of predictors without allowing the good or bad outcomes to bias either entry into the study or the assessment of the presence or absence of the predictors, and 3) verify the interview findings by comparing them with records. Work using these epidemiological methods has produced important new insights into the causes of psychiatric disorder and childhood problems and into the effectiveness of various treatments, but much work remains to be done.

Further research into the causes of childhood problems and mental disorders and the effectiveness of prevention and treatment is not superfluous. Those opposed to the continuation of research on children's psychiatric and emotional problems say that further research is unnecessary because the causes of children's problems are already known (they are due to lack of good schools and adequate health care, and so forth). Yet every careful evaluation of efforts to provide the services that are supposed to prevent children's problems has shown that they do not produce any significant long-term benefits. Children have not stopped developing psychiatric problems, school failure, or delinquency when they are offered early childhood educational programs, reading clinics, dental care, special education, school lunches, and counseling. Either our explanations are wrong or our remedial techniques are ineffective. It would be a pity to call a halt to the effort to understand causes and to find effective preventive and treatment techniques. The question is whether we can continue to do the necessary research without harming our research subjects.

The protection of human subjects of follow-up studies can be achieved without the severe current regulations that obviate the best kind of scientific evaluation of preventive and treatment efforts. Rigorous research on social and familial factors in psychopathology and on treatment *can* be done with the most minimal risks to the children or patients involved.

SAMPLING SOURCES

How do current regulations interfere with good research? Let us consider trying to determine the causes of deviance and psychiatric problems in children. Studies of this kind must begin with a general sample

Presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976

Dr. Robins is Professor of Sociology in Psychiatry, Washington University School of Medicine, 4940 Audubon Ave., St. Louis, Mo. 63110.

so that it will include children both who will and who will not develop problems. Entry into that sample should be unbiased with respect to the chance of having problems currently or in the future. This means that it should also be unbiased with respect to the chance of coming from families with problems, since we know that problems tend to be passed on within families. A treated sample is not useful because *all* of its members have problems, and thus we cannot learn how those with problems differ from those not affected. We cannot rely on comparisons of treated children and normal children because we know that treated children are not a random sample of all children with these problems. Entering treatment depends on the facilities available, social status, and family attitudes as well as on the severity of the disturbance.

The best sample to use to seek answers about causes is one selected from rosters representing a general population—rosters prepared *before* the population being investigated had any difficulties. Excellent rosters for such purposes are birth records or early school records, since the subjects' chances of appearing in these rosters will not have been affected by later psychiatric or behavior problems. Much of the research I have done has been based on random samples from elementary school records. With the passage of new laws and regulations, these records are simply no longer available.

In the course of a study of Viet Nam veterans and matched nonveterans (1), my associates and I wrote to schools located in the same zip code areas in which the veterans had lived at the time of induction, requesting the school principal to choose a control subject from among his alumni of the same age and level of education as the veteran at the date the veteran was inducted. The letter pointed out that we were *not* requesting school records. All we needed was the name, last address, and parents' names to help in locating the man in case his address was no longer current. We would then write the selected man and invite him to participate in the study. He would be free to do so or to refuse.

Most of the small town schools cooperated. Most of the big city school systems, however, declined to cooperate with our project—not because they disapproved of the study or feared that it would violate the privacy of their alumni, but because they feared that if they cooperated they would lose federal funding. One principal explained, "We know you are all right, but we can't even give out addresses from school records. After all, you might be trying to collect a bill from somebody." I pointed out that *he* was providing the name, not I, so there was no way I could be tracking down a "skip." That made sense to him, but he still did not help because there was a regulation and he could not violate that regulation regardless of the fact that my purposes were not the ones the regulation was written to protect students against.

With school and birth records unavailable as sampling sources, one alternative is to conduct area surveys. In the typical area survey, a representative sample of dwelling units is selected, the occupants enumerated, and one occupant chosen at random for interview. This is a poor choice when doing studies of psychopathology, deviance, or serious illness. In the first place, people with these problems have higher death rates than does the general population. Area surveys cover only survivors, thus omitting the most serious cases. In the second place, deviant and some psychiatrically disturbed people have lifestyles that make them relatively less accessible for such surveys. More are in hospitals and jails, and more do not have fixed addresses. The researcher is unlikely to find them at home by ringing doorbells. Thus the area surveyor gets a sample biased in favor of normal or neurotic people and loses the psychotic and socially deviant subjects.

FOLLOW-UP

The researcher needs access to records for reasons other than choosing an unbiased sample. Records permit him to assess possible causal predictors objectively, locate persons for interview, and objectively evaluate outcomes. People with problems who are interviewed about their childhoods are likely to remember selectively or to exaggerate memories that make sense of their current situation. Using records collected before their problems occurred avoids "retrospective falsification." In evaluating treatment or preventive programs, the researcher must compare persons who have and who have not had contact with them in order to determine whether their participation in the programs made a difference in the course of their illnesses.

Treated subjects and controls must be contacted sometimes years after exposure to the programs. In the past, skilled researchers have been able to find almost everyone designated. (Our own location rates have been 92–98% after 25 or 30 years.) It is important to locate almost everyone because *ease of location* is highly correlated with outcome. Subjects with the worst outcomes will be dead and thus locatable in vital statistics; subjects with the best outcomes will be listed in the telephone directory. The rest will be difficult to find. To locate subjects we used hospitals, police, drivers' license bureaus, credit rating corporations, school alumni offices, and a host of other formerly public records. All of these sources are no longer available without written permission. The difficulty with obtaining written permission is that not only is it difficult to anticipate all of the record sources for which permission ought to be sought, but permissions given are now valid for only *6 to 9 months*. Clearly, this makes long-term follow-ups impossible. A second problem is that the researcher often has no contact with his control subjects before the time he is ready to contact them to evaluate their outcomes, and thus he has had no opportunity to request their permission to examine records helpful in locating them.

STUDIES OF CHILDREN

The problem of long-term follow-up studies is particularly critical in research on children. As an example, it is important to know whether prescribing amphetamines for hyperactive children might be associated with illicit use of this or other drugs later on. The opposite possibility, and perhaps one just as likely, is that treatment of hyperactivity prevents the development of delinquent behaviors of all kinds and thus reduces the risk of drug abuse in adulthood. A reasonable study design to answer these questions calls for following hyperactive children treated with amphetamines into later life and comparing their outcomes with those of hyperactive children who did not receive drug therapy. At the present time school and police records could not be used either as address sources to help locate these children as adults or as measures of their outcomes. Permissions do not remain active long enough, and certainly a parent's permission will not be valid once the child is adult. Having to obtain permissions after the children have grown up is almost certain to mean a high rate of refusals and probably a seriously biased sample, since cooperation *after the fact* may well vary with the favorableness of the outcome.

THE FAMILY STUDY

Another valuable kind of study that has become virtually impossible under current regulations is the family study. Starting with parents with and without problems, for instance, the research wants to learn whether children separated early from a problem parent grow up to have higher problem rates than children from normal families, and whether they have lower problem rates than children reared by their problem parents. Formerly, it was not difficult to check school, hospital, and police records for the offspring to answer these questions without having to intrude on the families at all. Under current regulations this study could not be done without obtaining consent from each family member to check his records. Given this requirement, the chances of surveying the records for *all* members of a family become remote. Obtaining the consent of all family members is important if those without problems are more (or less) likely to consent than those with problems. And what if one of the offspring has been committed to an institution? Under current regulations it is not even clear that he is allowed to give his permission.

When families have split up and parents remarried, the problem of locating the child to request his consent becomes not only difficult but potentially upsetting to the people involved. We did such a study before the enactment of regulations about the privacy of records (2). We interviewed fathers and asked for the names of their wives and children. We then sought the names of the whole family in school and police records 10 years later and are now tabulating similarities between parents' and children's records under various conditions, such as when children did and did not live with the parent at critical ages. Some of these men were divorced when we first interviewed them, and many more have been divorced since then. Some of the children about whom they told us 10 years ago were illegitimate. Consider the relative risk to the people involved of what we actually did, i.e., making statistical tables from their records, versus what would have happened if we were to attempt that study now. We would have to appear at the man's home, where his current wife may not even know about his previous marriage or illegitimate children, to ask how to locate these grown children in order to seek their consent to examine their records. Future divorces might be partly *our* responsibility!

DISCUSSION

Much of the research on psychopathology and deviance for which records are needed carries no risk to the individual studied *unless* confidentiality is breached. Yet researchers are burdened with consent regulations designed to protect human beings when their participation in research requires taking potentially dangerous drugs or undergoing painful procedures. For such studies, the ability of children and the mentally disabled to consent *is* a difficult ethical question. The privacy regulations were not designed with research in mind but rather to protect persons from losing jobs or being sued when unauthorized persons read discreditable things about them in records. Unfortunately, these regulations fail to make a distinction between the researcher, who is interested in a person only as a representative of a class of persons, and employers or creditors, who are interested in him as an individual. These regulations, which are supposed to protect human subjects, have reached the point where the researcher's very *act of compliance* with the regulations while doing follow-up studies is likely to do the subjects more harm than are the research procedures themselves. Surely something is amiss.

We need to preserve access to records for research purposes; it is also important to combat the increasing tendency to destroy records. In the study previously described, in which my associates and I examined delinquency rates across generations, we waited until the children were past the age of risk of becoming delinquent before examining their records, to ensure that all cases of delinquency that would ever occur could be located. It turned out that the computer tape containing juvenile records was erased as soon as the child passed the age at which he could be arrested as a juvenile, in order to "protect" him. Luckily, one old-fashioned member of the juvenile court could not bring himself to destroy the cards on which the computer record had been based and had thrown them into the bottom of a file drawer, so the project was saved.

Such destruction of records is not simply a matter of conserving space, but has been recommended as a way of reducing the chance of records getting into the wrong hands. This view ignores the possibilities of using records for scientific as well as administrative and treatment functions. The record destroyers think they know when records have outlived their usefulness. As Dr. Otto Marx, a psychiatrist and medical historian, warned at an American Psychiatric Association conference in 1974:

> let us . . . stop the destruction of records wherever we can. The problem of confidentiality will not be solved by having no records of a confidential nature and nothing confidential in our records. . . . When fear of abuse leads to the destruction of record information, we are cheating future generations out of their heritage. Let us spend our energies on devising the means to maintain confidentiality within the new technology so that our own and future generations can benefit from technological advance (3).

Recent regulations have been offered in the name of ethics. But there are ethical problems other than those of consent and confidentiality. Sick children and the mentally disabled have a right to treatments and preventive health measures of proven effectiveness so that their lives and futures will be safe. There is no way to be sure that new treatments or preventive efforts are effective and safe without rigorous research and long-term follow-up studies. The issue of confidentiality is not insuperable. Researchers must be required not to disclose data about individuals, but most researchers want very much to preserve the privacy of the subjects who make their research possible. There are already a number of rather simple methods to do so. Let us find ways of protecting privacy without depriving future generations of the knowledge that could spare them unnecessary anguish.

The Functions of Human Subjects Review Committees

BY BRADFORD H. GRAY, PH.D.

After summarizing the literature on the functioning of committees set up to review research involving human subjects, the author describes three latent or emerging functions of these committees. These include using the committees to protect institutions, to judge proposed research in terms of possible social policy impact, and to consider proposed research from the standpoint of "community acceptability." The author expresses concern about the possible politicization of review committee decisions.

WE ARE ALL AWARE of the great interest that has developed in recent years in the complex issues raised by research involving human subjects. Many slips can take place in the application of general principles or guidelines to particular situations. Thus there is general agreement—reflected in the regulations of the U.S. Department of Health, Education, and Welfare—that when a research project entails risk to subjects the judgment of the investigator regarding the rights and welfare of subjects should be reviewed by people who have no vested interest in the research. However, very little has been written about the specific mechanism—human subjects review committees—that has been invented to play this role. The literature contains some information on the background and development of

Presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Gray is Staff Sociologist, National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, Westwood Bldg., Rm. 125, 5333 Westbard Ave., Bethesda, Md. 20016.

The views expressed in this paper are the author's and do not necessarily reflect the views of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research or any other individual associated with it.

this regulatory approach (1, 2), descriptions of the procedures and problems of a few committees (3–6), and some limited empirical studies of such committees (7–10).

Rather than discussing the well-known duties of human subjects review committees as set forth in DHEW regulations (see appendix 1), I will examine some functions that might be described as unintended, latent, or emerging. It might be useful to begin with a brief summary of what we know about human subjects review committees, although the committees whose experience has been shared in the literature hardly comprise a representative sample. (This and many other weaknesses of earlier studies should be corrected in a study that is under way for the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research.[1])

The literature suggests that the major issues being dealt with by review committees pertain to the risks of research and to informed consent; I believe that the latter is often dealt with too narrowly by focusing on consent forms and overlooking the setting in which consent is obtained (11). Melmon and associates (5) reported that the medical school at the University of California, San Francisco, found agreement among independent subcommittees in the rejection of a small number of proposals on the basis of excessive risk or inadequately evaluated risk. I know of no other information on the reliability of committee decisions.

Disagreement has been reported between committees and investigators over the legitimacy of review committees being concerned with adequacy of scientific design. It appears that in some cases investigators are beginning to accept the view that faulty research design is a legitimate matter of concern to human subjects review committees, particularly when subjects are to be put at risk, but this remains a thorny topic.

Finally, to conclude this brief survey of what review committees do, I should mention two problem areas. First, although it is often cited as being very important, continuing review or monitoring is not very extensively developed in either regulations or practice. There seems to be little general agreement on what sort of activity by a review committee would be appropriate in this area. The second problem is suggested by anecdotal reports of special difficulties created when research from one field is reviewed by a review committee accustomed to different research models. This indicates that there may be too much rigidity in carrying out the review function at some institutions.

One must be very careful in talking in evaluative terms about the functioning of review committees because there is no absolute standard against which to measure performance. Elsewhere (8) I reviewed the evidence for the impact of human subjects review committees. For this study my primary sources of data were the survey by Barber and associates of almost 300 review committees (7) and my own intensive study of a single review committee (11). My conclusions were not reassuring with regard to the general adequacy of the performance of review committees. However, I would prefer not to go into those data again, both because they are fairly well known and because they are several years old. The results of the study currently under way for the National Commission for the Protection of Human Subjects should enable us to discuss these matters more intelligently.

If one judges from what review committee members have said and written elsewhere, it appears that at least some committees have been growing in sophistication about the issues involved in human experimentation, in the stringency of their review, and, interestingly, in their acceptance by investigators. It is difficult to say whether their acceptance by investigators reflects a positive response to being helped with difficult issues, a perception that their interests are being protected, or simple resignation in the face of an unavoidable intrusion.

There seems to be general agreement now that review committees have a proper and important role in research involving human subjects. Current discussions tend to be about how they can be improved rather than about whether they are legitimate. The legitimacy of these committees is an important problem that is central to their successful functioning. The committees must have legitimacy in the eyes of investigators if compliance with the spirit of their activities is to be expected. There must also be legitimacy in the eyes of outsiders, whether they be the general public or legislative bodies, if current doubts about the propriety of research involving human subjects are to subside.

It is from the perspective of a belief in both the importance of the role of review committees in protecting human subjects and the importance of a high degree of legitimacy in the eyes of investigators and the public that I want to express some concerns about three unintended, latent, or emerging functions of these committees.

UNINTENDED FUNCTIONS OF REVIEW COMMITTEES

My first concern pertains to the uses to which the review procedure is put. A safe assumption with any control procedure in a bureaucratic structure is that it will tend to be used for purposes other than that for which it was designed. The review procedure can be used for its manifest purpose of protecting human subjects, but it can also be used to protect investigators or to protect institutions. These functions are not necessarily inconsistent: true protection of subjects would also protect the investigator and the institution. However, actions that protect the investigator or the insti-

[1]Although I have been closely associated with this study, which is being conducted under contract by the Survey Research Center at the University of Michigan, this paper was presented before the completion of the study and is not based on it.

tution may have little to do with protection of human subjects. (There is an element of this in the use of consent forms in some instances.)

In universities, the research activities of faculty have in the past been under rather minimal control of the institutional administration, but there are countervailing "rationalizing" pressures to curtail such independence. It would be understandable if institutional officials used their influence on or control over review committees to have them consider proposals from the standpoint of what is to be gained or lost by the institution if the research is done. This may have little to do with the protection of human subjects and a great deal to do with avoiding controversy. The extent to which such criteria are now applied to proposals is unknown; only anecdotal evidence is available. This problem, however, relates more to the way that review procedures are made operational than to their theory or concept and could perhaps be controlled through appeal procedures.

My second concern pertains to whether review committees should consider in their deliberations the implications of proposed research, particularly their social policy implications. Stated another way, should review committees weigh, as a negative factor, the uses to which the results of research might be put? This issue has been labeled the social risk issue because the words "social risk" in DHEW regulations have on occasion been interpreted as requiring or legitimating the consideration of such factors by review committees. In two situations in recent years such criteria were applied in National Institute of Mental Health study sections and produced a flurry of spirited correspondence. Although letters of clarification were eventually sent from NIMH and the National Institutes of Health's Office for Protection from Research Risks stating that study sections had no authority to apply such criteria, the letters indicated that there is considerable pressure to enter such considerations into the review process.

It is obvious that the application of such criteria would in many (perhaps all) situations be antithetical to established conceptions of free and open inquiry. Thus it requires justification. (This, of course, does not suggest that such considerations should not enter into decisions regarding allocation of public funds.) In addition, there is no reason why such social consequences of research should be considered only if human subjects are involved. Put another way, there is no reason why such considerations should enter into the human subjects review process, even if a public policy decision were to be made that research should be done only if the anticipated consequences of the study have some proper risk: benefit ratio. Such consequences have nothing to do with the presence or absence of human subjects in the research.

The third emerging function I wish to raise is actually found in DHEW regulations, although its meaning there is not very clear. The regulations require that the membership of human subjects review committees be able to determine whether research is acceptable in terms of "community attitudes." Over the past 10 years there has been a trend in the regulation of human experimentation away from a peer review model toward a review model that includes more lay representation. Robert Veatch, a bioethicist, characterized this as a movement from a professional model toward a jury or representative model (12). Veatch argued that confusion exists over what human subjects review committees are supposed to do. Certain tasks call for professional expertise and suggest one type of committee composition. On the other hand, there is, in Veatch's words, a "growing recognition" that committees must "have the ability to judge community attitudes and community acceptance," tasks that call for a membership that is representative of the community. Veatch did not examine the desirability of these developments.

As far as I can determine, the idea that human subjects review committees should judge whether research is acceptable in the light of community attitudes and the implications that follow from this idea have received remarkably little serious comment and analysis. The purpose of community representation on review committees is not clear. DHEW regulations, for example, do not specify which judgments should involve community attitudes; this leaves doubt about whether a shift has occurred in the functions review committees are to serve. If the function of community representatives is to keep the process honest, to look at consent procedures from a layperson's perspective, and to broaden the viewpoint from which judgments of acceptability of risks and benefits are made, no shift may be involved and lay representation may strengthen the process. However, if the function of community representation is to decide whether a community would find the study immoral, to judge the acceptability of policy implications of proposed research, or to determine whether the interests of certain organizations or groups are affected by the research, then a shift will indeed be involved. These decisions are essentially political, and their inclusion in the human subjects review process would fundamentally change its nature and purpose.

CONCLUSIONS

The politicization of human subjects review procedures may be inevitable, but it may weaken their effectiveness in functions related to the protection of human subjects, either by drawing attention away from human subjects issues or by reducing the legitimacy of review procedures with investigators. Thus there is reason for concern about developments that move the process in the direction of a political model of review, whether the impetus comes from the government or from the research community itself, which may seek to use the process to defend the researcher who has become involved in controversy.

APPENDIX 1
U.S. Department of Health, Education, and Welfare Regulations on Human Subjects Review Committees

The DHEW regulations (45 CFR 46) require that the following determinations be made by review committees:

[The] review shall determine whether these subjects will be placed at risk, and, if risk is involved, whether:

(1) the risks to the subject are so outweighed by the sum of the benefit to the subject and the importance of the knowledge to be gained as to warrant a decision to allow the subject to accept these risks;

(2) the rights and welfare of any such subjects will be adequately protected;

(3) legally effective informed consent will be obtained by adequate and appropriate methods in accordance with the provisions of this part; and

(4) the conduct of the activity will be reviewed at timely intervals.

Federal Constraints: Earned or Unearned?

BY DONALD T. CHALKLEY, PH.D.

The author discusses the evolution of federal constraints on medical, behavioral, and social science research. There has been only one court decision related to behavioral research and none in medical research. The burden of consent procedures can be lightened somewhat by careful consideration of the potential risks and nature of the research; questions are presented that can be used to determine whether constraints apply. The author notes that although there are good reasons for regulations in both behavioral and medical research, the appropriateness of current and proposed constraints is still a matter of debate.

IN THE ACCOUNT that follows, I have attempted to be factual, with no imputations of profession-wide insensitivity, lack of ethical probity, or actual guilt. No court could convict any of the research professions as a whole on the basis of the few examples of individual misconduct that have disgraced the pages of investigational history. In the 200-year history of medicine in the United States, no physician has ever been found guilty of "malresearch," although malpractice decisions number in the few thousands annually. In fact, there has been but one malresearch decision under all of English common law. This case, *Halushka v. University of Saskatchewan* (1), involved a student who volunteered for a trial of a new anesthetic.

There has been only one decision in the behavioral sciences, but this was a United States case in the Federal Court for the Eastern District of Pennsylvania. The case, *Merriken v. Cressman* (2), has medical overtones since it was concerned with drug usage, but the research techniques were purely behavioral.

Dr. Chalkley is Director, Office for Protection from Research Risks, National Institutes of Health, Westwood Bldg., Rm. 303, 5333 Westbard Ave., Bethesda, Md. 20016.

The opinions expressed herein are those of the author and do not necessarily reflect the views of the National Institutes of Health, the Public Health Service, or the Department of Health, Education, and Welfare.

Editor's Note: All of the preceding papers in this Special Section were presented at the 1976 annual meeting of the American Psychiatric Association in a session titled "Freedom of Inquiry and Subjects' Rights." In the interest of a balanced presentation, the Editor invited Donald Chalkley, Ph.D., Director of the Office for Protection from Research Risks, National Institutes of Health, to write a paper presenting some background information about why constraints on behavioral science have been imposed by the government.

Michael Merriken was an eighth-grade student in Norristown, Pa., and Wilmer D. Cressman was head of the Montgomery County, Pa., Board of Commissioners. The Board planned to introduce a drug addiction prevention program to aid the local school district in the identification of potential abusers and "to change the cognitive and affective domains of potential drug abusers and other forms of deviant behavior." Candidates for the program were to be identified by questionnaire, and student participation was to be required in the absence of positive parental objection. Many of the questions were directed toward familiar and sensitive issues: religion, race or skin color, political differences, differences in aggressive tendencies, unusual or odd behavior, and so on. The information was to be compiled in a "massive data bank" available to school employees, social workers, PTA officers, and school board members.

The Court's opinion discusses Constitutional guarantees of privacy, noting that "the right to privacy is on an equal or possibly more elevated pedestal than some other individual Constitutional rights and should be treated with as much deference as free speech." The "right to investigate" is sometimes equated with free speech, so this comment by the Court takes on an unusual significance. The Court then turns to the issue of consent, emphasizing that "in the case at Bar, the children are never given the opportunity to consent to invasion of their privacy; only the opportunity to refuse to consent by returning a blank questionnaire. . . . Whether this procedure is Constitutional is questionable. . . ." Citing the Supreme Court in *Brady v. United States* (3), "Waivers of constitutional rights not only must be voluntary but also must be knowing, intelligent and done with sufficient awareness of the relevant circumstances or likely consequences," the Pennsylvania Court concluded that attempts by the defendants to obtain consent would have been adequate if they had been comparable to the consent "ideally obtained by a physician prior to the performance of surgery," which does not quite equate the risks of behavioral research with those of clinical investigation but comes uncomfortably close to it.

Despite its potential significance in the hands of a plaintiff's attorney, *Merriken v. Cressman* has had little impact so far on the development of policy, regulation, and law with respect to behavioral research. Historically, concerns appear to have arisen out of public clamor that is often communicated through the Congress in terms of statements to the media, interaction with federal agencies, or the passage of legisla-

tion. The original version of the present Department of Health, Education, and Welfare policy, now codified as Part 46 of Title 45 of the Code of Federal Regulations, was a Public Health Service policy document, "Clinical Investigations Using Human Subjects" (Policy and Procedure Order 129, dated February 8, 1966) that was concerned solely with clinical investigation. On February 9, 1966, Representative Cornelius Gallagher, Chairman of the Special Subcommittee on Invasion of Privacy, wrote to Philip R. Lee, M.D., Assistant Secretary for Health and Scientific Affairs, asking for documentation of an earlier assurance by the Public Health Service that any federally supported research project using personality tests, inventories, or questionnaires would be done only with informed consent by or on behalf of the subject. Similar assurances had also been sought by Representative Reuss of the Committee on Government Operations (4). This, among other matters, led to a revised version of Policy and Procedure Order 129 on July 16, 1966, which made the order broadly applicable to all investigations involving human subjects, including clinical research. On September 13, the involvement of nonclinical investigations was made even more explicit by the issuance of a supplement entitled "Considerations in the Behavioral Sciences." This was followed on December 12, 1966, by a clarifying memorandum reflecting discussions with the American Psychological Association and other organizations representing the behavioral sciences. Much of the language of this memorandum was later incorporated into DHEW policy published in 1971 (5).

Here the matter stood until 1973. In the latter part of the 93rd Congress, unfavorable publicity surrounding the so-called Tuskegee case (6) led to a rash of Senate bills designed to establish controls on human experimentation. One of these bills (Senate Bill 878) dealt with human experimentation generally, another (Senate Bill 934) was concerned solely with medical experimentation, and a third (Senate Bill 2072) was designed to "assure maximum protection for human subjects of biomedical and behavioral research." This phrase was incorporated into the title of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, established by the National Research Act (P.L. 93-348).

The foundation of behavioral studies against which Representatives Gallagher and Reuss and Senator Edward Kennedy based their concerns is none too consistent. Committee prints issued by Representative Gallagher's special subcommittee in 1965 (7) are concerned principally with data gathering and the privacy issue. The 1967 Reuss committee was concerned with social science studies in such areas as crime and law enforcement, education, poverty, welfare, and social aspects of medicine and health (8). The latter specifically touched on behavioral research supported by NIH and NIMH. In 1970, Representative Gallagher explored the use of drugs in treating hyperkinesis (9). The Kennedy hearings touched on behavioral issues only peripherally in connection with psychosurgery and drug use (10). Separately, none of these hearings or studies provided a broad basis of fact for regulation of the behavioral sciences.

There is, however, reason to believe that such evidence could have been found had these hearings and studies been designed to look for it. A continuing study of the confidentiality of social science research sources and data sponsored by the Russell Sage Foundation[1] has identified a substantial number of cases involving advertent and inadvertent breaches of confidentiality by researchers in the behavioral sciences. Most of the cases cited are abstracted from the American Psychological Association's publication "Ethical Principles in the Conduct of Research with Human Participants" (11). Many are clearly recognizable and one could identify the institution and persons involved, but the implicit confidentiality of the study and of the "Principles" should be honored. As one member of the confidentiality study staff noted (12), "Not all involve litigation . . . although most of the nonjudicial cases *could* have involved such interests" (emphasis in the original).

These case citations are indefinite as to time, type of institution, nature of support, and prior collegial or review board consideration. A more general source of evidence on the frequency of problems involving human subjects can be found in the files of the NIH Office for Protection from Research Risks. For calendar 1976, some 15,437 applications were referred to NIMH and NIH for review at the March, June, and October National Advisory Council meetings. Of the 12,988 referred to NIH, 265 (2%) were criticized by reviewers in terms of the proposed handling of human subjects; 62 of the 2,449 applications referred to NIMH (2.5%) were similarly criticized. The difference is not statistically significant.

This is, of course, a soft statistic. There are differences in approval rates by institutions, in sensitivity to problems (a group of oncologists is undoubtedly less sensitive to certain issues in the use of narcotics to create euphoria in cancer patients than would be a group of psychopharmacologists), and in the types of issues raised. In addition, NIMH reviewers appear to be far more sensitive and active with respect to criticisms of informed consent procedures. Nevertheless, it is interesting that judgment of the problems in their respective fields by separate if not distinct groups of peers has resulted in about the same level of criticism.

There is a principle of the law that states simply *respondeat superior*—literally, "let the master answer," which originated in a challenge in the Roman courts to a master to account for the wrongful acts of his ser-

[1]This information is contained in an unpublished February 25, 1975, progress report to the Russell Sage Foundation of the American Political Science Association study "Confidentiality of Social Sciences Research Sources and Data." It should be noted that most of the publications emerging from this study have been concerned with the problems encountered by investigators in trying to protect confidentiality.

vants. Today it establishes the responsibility in certain circumstances of an employer, i.e., an institution, for the acts of its employees, staff, or faculty. The original Public Health Service policy, laid down in 1966 and continued roughly through 1973, established a formal system of institutional review boards to assure that this responsibility was recognized when an institution proposed to apply for a research grant or responded to a request for a contract proposal. The areas of concern were spelled out, the institution was required to develop or adopt its own set of principles and to adhere to its own regulation, to standards of professional practice, and to the applicable law, and to be alert to the concerns of its community. Details were sparse.

Unfortunately, old policies seldom die—they just become more complex. Initially, the lack of a formal position on research involving human subjects was looked on as a missing link in our policy chain. Once that link was forged, it was immediately evident that there were now missing links between that link and the rest of the chain—links with respect to different classes of subjects, different types of experimentation, etc. Each critic can find a link absent in his immediate area of concern; each investigator can find a reason why his immediate area of research should not be unduly restricted. The potential beneficiary of research can only wait for the resolution of the dispute.

The existing regulations were designed to permit institutional review boards a substantial amount of latitude. Before assuming the "constraints," any board should ask itself several questions, some of which are listed below.

1. Is the project really a research and development proposal? Or is it simply a service or other activity using techniques commonly associated with behavioral research but not intended in a particular instance to serve a research function? If the answer to the first question is no, the regulations do not apply.

2. Does the project involve risk? If the project involves the analysis of data already in existence that cannot be linked to personal identifiers, if it involves public observation of unidentified and unidentifiable persons, if the methods are entirely standard and accepted and applied solely to meet the needs of the subject—even if supported by research funds—no risk is involved and the review can be curtailed.

3. Does the project involve only minimal risk? Would full written or oral consent invalidate the study's objectives? Would any alternative means for obtaining these objectives be disadvantageous to the subject? If these conditions apply, the consent requirements can be modified or omitted altogether. Certainly, in many behavioral studies in the areas of psychosomatic medicine, clinical psychology, etc., these conditions do apply, with a consequent reduction in the burden of consent.

There are as many good reasons for constraints in behavioral research as there are in medicine. Whether the constraints currently imposed or to be imposed in the future on either field of investigation are truly justified is a matter for continuing debate. At the moment, we are busy dismantling the wall of protection we seek to build around those in need of the benefits of research while we devote much time and effort to erecting protections for the subject. The time and effort of any person is limited. Some compromise may be necessary.

Effect of Diet on Urinary MHPG Excretion in Depressed Patients and Normal Control Subjects

BY GIOVANNI MUSCETTOLA, M.D., THOMAS WEHR, M.D., AND FREDERICK K. GOODWIN, M.D.

The authors studied the effect of a catecholamine-controlled diet on the urinary level of 3-methoxy-4-hydroxyphenylglycol (MHPG) of 6 depressed patients and 6 normal volunteers. The normal subjects showed no change in MHPG levels on or off the diet; the depressed patients showed a significant increase in MHPG while off the diet.

THE PURPOSE of this study was to examine the effect of dietary alterations on the urinary excretion of 3-methoxy-4-hydroxyphenylglycol (MHPG), an important norepinephrine (NE) metabolite, in depressed patients and in normal control subjects. Initially on the basis of indirect evidence suggesting the involvement of NE in the mechanisms of action of mood-altering drugs, it has been hypothesized that NE, a catecholamine neurotransmitter, may be involved in the pathophysiology of major affective disorders (1–3). To evaluate this hypothesis directly in patients, a number of groups have studied the urinary excretion of amine metabolites, principally that of MHPG, the major metabolite of NE in brain. A clinical study from our laboratory using isotope dilution techniques indicated that most of the MHPG in urine originates from brain NE metabolism, whereas virtually all of the 3-methoxy-4-hydroxymandelic acid (VMA), the other major metabolite of NE in urine, comes from the periphery (4).

In studies of affective disorders, one group (5) reported that urinary MHPG, but not VMA, was low in patients with endogenous depression compared with control subjects; another group (6) did not find this difference. Another study (7) reported that urinary MHPG, but not VMA, increased on the patient's recovery from depression. In addition, MHPG has been reported to be higher in the manic phase than in the depressed phase of bipolar affective illness, although there is disagreement as to whether the increase in MHPG precedes or follows the onset of mania (7–11). Because of these discrepancies and also because of the possibility of subgroups with different patterns of MHPG excretion (6, 12, 13), it has become important to evaluate such sources of variance as diet (14).

A variety of foods, particularly some fruits and vegetables, are known to contain preformed catecholamines (15–17). Although a 1959 study showed that ingestion of large amounts of bananas produced an increase in total urinary catecholamines in normal control subjects (18), subsequent studies in normal subjects have indicated negligible dietary influences (17, 19–21). To our knowledge the effect of diet on urinary catecholamine metabolites in depressed patients has not been reported.

METHOD

Six depressed patients (5 women and 1 man) and 6 normal volunteers (all women) were studied on a metabolic research ward at the National Institute of Mental Health. All of the subjects adhered to a special low-monoamine diet (see appendix 1) from the time of their admission; after at least 3 weeks all of the subjects were taken off this diet for 7 days, during which time they were encouraged to eat the previously restricted foods (with the exception of alcohol, which was excluded from the entire study). Following this off-diet period they were returned to the low-monoamine diet. Both diets were specially prepared and supervised by a trained National Institutes of Health dietician. The 6

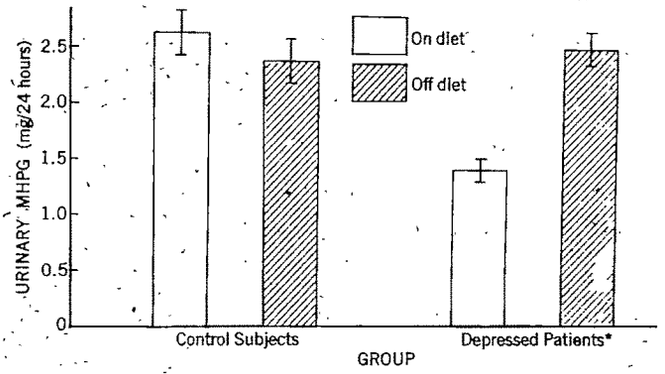
*Number of 24-hour samples.

normal volunteers were free of psychiatric symptoms or history. Of the patients, 5 were moderately depressed and 1 was severely depressed. One patient was receiving a placebo, and 5 were receiving various drugs as indicated in table 1; no medication changes were made during the study. Global ratings of depression, anxiety, psychosis, anger, and mania were obtained twice daily by consensus of a nursing research team using a modified Bunney-Hamburg Scale (22).

Twenty-four-hour urine samples were collected throughout the study. Completeness of urine collection was monitored by a urine loss recording system; any questionable collection was discarded. Urine was refrigerated within 30 minutes of voiding, and aliquots were frozen at −20° C within 3 days; urinary MHPG has been shown to be stable under these conditions (unpublished observations by F.K.G. and C.C. Jones). Samples were selected from 3 to 5 days during the week preceding the change in diet, 5 to 7 days during the period off the diet, and 1 to 4 days during the week after resumption of the low-monoamine diet. MHPG was analyzed by electron capture gas liquid chromatograph using a modification of the method of Dekirmenjian and Maas (23).

RESULTS

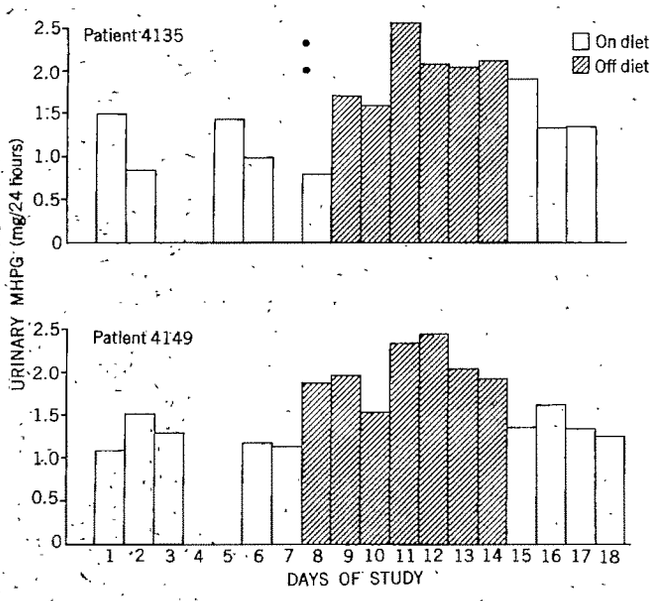
No overt behavioral or mood changes could be detected in either group during the period of the study, either as reflected in the global ratings or by clinical observation. The MHPG data for individual patients are shown in table 1, and the overall results are summarized in figure 1. For the normal control subjects there was no change in urinary MHPG during the period off the controlled diet. On the other hand, the mean urinary MHPG in the depressed patients increased by 80% during the off-diet period ($p<.01$ by paired t test). Two typical patterns of daily MHPG excretion throughout the study are shown in figure 2. There was a large variability in the time course of the individual patients' responses to discontinuation of the low-monoamine diet; 2 patients showed a dramatic increase after only 24 hours on the high-monoamine diet, while 3 other patients took a longer period of time to show this increase. When the low-monoamine diet was reinstated, the urinary excretion of MHPG of all patients returned to baseline levels in 1 to 3 days.



DISCUSSION

It is obvious that the amount and kind of food intake as well as the ability to cooperate with dietary restrictions can vary widely in different phases of affective illness in the same patient. Individual patients may also vary considerably in the duration and severity of appetite disturbances associated with their illness. Therefore, state-dependent differences in urinary MHPG excretion reported to exist in affective disorder must be cautiously interpreted until the relative importance of variations in monoamine ingestion—even in patients on restricted diets—has been determined.

The unique responsiveness of urinary MHPG to changes in dietary amines in depressed patients compared with normal control subjects is intriguing; we have no satisfactory explanation for it. Behavioral factors thought to be associated with MHPG excretion, such as mood state and anxiety, did not appear to change during the course of the study. However, we cannot exclude the possibility that the dietary change had a different meaning for the patients than it did for the control subjects; there may have been some subtle alteration in the patients' emotional state accompanying the experience of being off the diet. Alternatively, we might hypothesize that these patients have some impairment in noradrenergic "buffering" mechanisms, rendering them more vulnerable to dietary changes.



Whatever the explanation we are left with the conclusion that normal control subjects may not be suitable for evaluating the contribution of some potential

APPENDIX 1
Low-Monoamine Diet

Excluded beverages: chocolate, cocoa, wine, beer, alcohol, orange juice

Excluded fruits and nuts: banana, avocado, pineapple, plum, prune, orange, walnut, raisin, fig

Excluded vegetables: tomato, broad bean, eggplant

Excluded meats, dairy products, and fish: chicken liver, herring, smoked fish, brain, aged cheese, sour cream

Community Psychiatry in Tutuila, American Samoa

BY WILLIAM E. WALTERS, M.D.

The author hypothesizes that the underreporting of mental illness in Tutuila, American Samoa, is a direct result of the social system, which provides a means of "curing" emotional disorder by family group process and shamanistic ritual, by making the disorder less disruptive, and by absolving the affected individual of personal guilt.

REFERRING TO MENTAL HEALTH problems in developing countries, Ari Kiev (1) said that what is needed is practical research on such questions as why patients with recognizable disorders fail to obtain available treatment and what makes indigenous treatments so effective. These questions have plagued the mental health staff of the LBJ Tropical Medical Center in Tutuila, American Samoa. According to the size of the population on this island (30,000 people) we should expect much more mental illness, but the mental health clinic's patients load remains light (see table 1). In an attempt to qualitatively identify the reasons for the population's underuse of mental health facilities we examined two factors: 1) family life, which is the sociocultural setting of all activity in Samoa, and 2) bush medicine, the traditional system involving belief in ancestor spirit (*aitu*) causation of most illness, a folk healer, or *taulasea*, and treatments that involve family prayer and certain herb remedies combined with the *taulasea's* intercession with the *aitu*, or spirit.

The basic sociocultural unit in Samoa is the *aiga*, or family. Samoans live in extended families of 6 to 30 members. Living space is crowded, and young people are aware of the facts of life early. Given this setting, one might think that there would be an accentuation of oedipal conflict and problems involving overclose, incestuous sibships. However, the large family group, in contrast to the Western nuclear family, seems to defuse the oedipal conflict. Brother-sister incest is not common in Samoa.

Fifty years ago Margaret Mead (3) noted that there were few cases of social unrest or mental problems in Samoa, except among people separated from their family by the stress of Western culture. Statistics are incomplete and unreliable, but the best indications point toward the fact that the major psychoses occur in about the same frequency in Samoa as they do in the Western world and in primitive cultures. This, despite rapid acculturation of Samoa to Western society, is consistent with Dunham's hypothesis concerning the independence of major psychoses from cultural variables (4).

The second feature of Samoan society that militates against recognizing mental illness and blurs the reporting of such problems as obsessional and hysterical neuroses is the concept of causation inherent in the *aitu* belief, a kind of ancestor worship holding that spirits return to haunt particular locations, where they may enter the bodies of unsuspecting victims. The offense to the spirit does not involve individual guilt. Rather, the family of the person who is stricken has offended the spirit. Thus the son or daughter may suffer for the transgressions of an elder, or *matai*.

This particular view of spiritual or mental trouble as a family problem has two important consequences: 1) it unites the family in support of the affected individual with a view toward expiating the offense and breaking the spell of the *aitu* through family prayer and visiting the *taulasea*, and 2) it offers a kind of built-in confessional whereby the guilt associated with mental illness is diffused over the entire family. The responsibility for disturbed behavior is removed from the patient and ascribed to the whim of an angry *aitu*.

Thus etiology, treatment, and prognosis of mental illness are all viewed in the context of family problems. Mental illness is a strange concept to Samoans; the disturbed person is seen as troubled rather than sick. The three following case examples illustrate Samoan attitudes.

CASE REPORTS

Case 1. A 15-year-old Samoan girl from a large family was brought to the medical center's emergency room because she had taken an overdose of 20 acetaminophen tablets. Her family disapproved of her 18-year-old boyfriend; her mother had forced him to leave the house, which resulted in a violent argument in which she struck the girl. The girl was very angry with her mother and developed a sudden headache. At the clinic the girl said that she took the overdose to rid herself of the pain.

The girl told us that this was not her first bad headache. She had been beaten by her brother in a similar quarrel two months before this episode and had been very angry at him. At that time she was seen by the *taulasea* for her head pain. He interpreted that the *aitu* of two girls who had died in a family feud had infected her. The *aitu's* name was

Dr. Walters is Director, Mental Health Division, LBJ Tropical Medical Center, Pago Pago, Tutuila, American Samoa 96799.

TABLE 1
Comparison of Projected Versus Actual Number of Mentally Ill Patients Seen in Tutuila

Diagnosis	Projected Number of Patients with Psychiatric Diagnoses 1973–1974*	Number of Patients Seen at Mental Health Clinic 1973–1975
Character disorder, personality disorder, adjustment reaction	366	105
Victim of child abuse	—	56
Neurosis, psychophysiological reaction	1,832	99
Schizophrenia, other psychosis	595	52

Alcoholism	137	6
Major affective disorder	320	—
Other, undiagnosed, deferred diagnosis	—	56

*According to the statistical survey of the South Pacific Commission, cited in reference (2).

Sauma'iafe. In order to expunge the spirit, he said, it would be necessary for the girl to drink some medicine and for relatives to pray over her. This the family had done. However, after the girl took the overdose of acetaminophen, the family concluded that she had not profited by their treatment. They had a large meeting and determined that the girl should be beaten for her recalcitrance. She determined to accept her fate.

Case 2. A young Samoan woman had been hearing alien voices for about two years; she had tried to ignore them. At the time she first heard the voices she was living in Michigan with her husband. When the voices became threatening, she phoned her mother, who went to Michigan and brought her back to the island. Here they consulted a *taulasea*, who prescribed that the bark of *fue sina* should be mixed with water and rubbed on the patient's body. The diagnosis was *ma'i ole mafaufau*, or acute psychosis caused by an *aitu*.

After undergoing the prescribed treatment the patient became worse; she was convinced that the *taulasea* was part of a plot against her. At that point her sister urged her to visit the medical center. When we first saw her this patient was delusional with very fragmented thinking, ambivalence, and a sly, fugitive manner. After a brief hospital stay and intensive use of chlorpromazine and fluphenazine, she was able to speak coherently. She showed marked deference to her father and the *matai* system but denied any belief in *aitu*. She wanted to return to her husband in Michigan but expressed great fear about leaving her family in Samoa.

Case 3. A young, single Samoan man was brought to the medical center by his brother. The patient had become ill two years before, while he was living in San Francisco. His present symptoms consisted of a wandering life-style, attempting to find "the answer," praying a great deal, and having the delusion that he was the messenger of strength, wisdom, or purity. He exhibited a flattened affect, showed thought blocking, and stared into space. He appeared in the interview to be hearing something and admitted to an auditory hallucination, coming from the Lord, which admonished him to see the truth.

Before this patient was brought to the medical center his family had consulted a *taulasea*, who pronounced him afflicted with an *aitu*. There had been a family council in which the *matai* adjured the village to admit which individual had cast the spell. The patient continued to exhibit religious delusions and was brought to the pastor, an important man in the village. This man recognized the symptoms of schizophrenia and suggested medical care. The family seemed rather cynical about the religious content of the delusion, and the patient was universally regarded as *ma'i ole mafaufau*.

A HYPOTHESIS

In response to Kiev's questions regarding why some patients with recognizable disorders fail to obtain available treatments in developing countries I would like to offer the hypothesis that these patients are often sheltered by their family and that there are cultural sanctions for some types of mental illness. According to 1973–1974 statistics gathered by the LBJ Tropical Medical Center, an estimated 595 cases of schizophrenia were projected for our island of 30,000 inhabitants (see table 1). This figure contrasts with an incidence of 34 cases of schizophrenia and 18 of other psychoses seen in the mental health clinic during 1973–1975. McCuddin (5) indicated that patterns of referral were often from one *taulasea* to another rather than to the medical center.

The fact that the *taulasea* is able to effect a cure when modern methods fail to is traceable to the cathartic effect and group spirit aspect of the *aitu* cure. The group ritual is also practiced in exorcism, as noted by Lambert in Samoa (6) and by León in Colombia (7). Garrison (8) also noted the universality of primitive medicine and ascribed its success to group cohesion and social expectations. Another aspect of this success is intrapsychic; the patient might possibly identify with the power and magic of the shaman's personality. Several treatments are usually necessary in this kind of medicine. The cure is often obtained by the combination of coercion and group support and abetted by the suggestibility of the patient. Thus the patient may remain symptomatic but nondisruptive, as in case 3.

CONCLUSIONS

The underreporting of mental illness in primitive cultures noted by many authors is present in the developing society of American Samoa. This is a direct result of the social system, which tends to view underperformance and quiet insanity with calm disdain. The success of the *taulasea*, or bush doctor, in treating mental disorders can be attributed to the group process, the cathartic effect of the patient's participation in family prayer, the absolution of guilt, and faith in the magic of the healer.

An interesting unanswered question remains: Was

the gentle, stable, and permissive culture of old Samoa less productive of mental symptoms than our Western culture? Incidence studies (8, 9) and records of our medical center would so indicate. In 1973–1975 the medical center admitted 24 native Samoan patients with a final diagnosis of psychosis. Twenty of these patients were schizophrenic (12 were catatonic or hebephrenic, 2 were simple, chronic, and undifferentiated, and 6 were paranoid). Two patients had dementia caused by organic brain syndrome, 1 had paranoia, and 1 had psychotic depression. All of the 6 paranoid schizophrenic patients became symptomatic while living off the island. Recent trends indicate that drug and alcohol abuse, suicide rates, and delinquency are all on the increase in Tutuila and the other Samoan islands (2, 9).

A Comparison of Outcome in Adolescent- and Late-Onset Bipolar Manic-Depressive Illness

BY GABRIELLE A. CARLSON, M.D., YOLANDE B. DAVENPORT, M.S.W., AND KAY JAMISON, PH.D.

The authors hypothesized that childhood- and adolescent-onset bipolar manic-depressive patients might have a more severe or a different type of affective disorder; early-onset patients were therefore compared with patients whose illness onset was after the age of 45. The results indicate that early age of onset is not a factor in the variable course and prognosis of manic-depressive illness.

ALTHOUGH THERE ARE references in older literature to the definite existence of manic-depressive illness in late childhood and adolescence, the problem of affective disorder in this age group has received little attention until recently, and its occurrence has been considered rare. However, one-third of Winokur and associates' bipolar patients became ill before the age of 20 (1); 40% of Perris' bipolar patients had onsets between the ages of 15 and 25 (2); and 20% of 2,000 manic episodes recorded by Wertham (3) began before age 20. The availability of definite treatment for depression and mania has made recognition of these disorders of more than theoretical interest, and efforts are being made to identify affective disorders in children and adolescents.

Criteria for establishing the diagnosis of bipolar affective illness in childhood were noted by Anthony (4) in 1960 and are similar to adult criteria (periodic, biphasic illness, family history of affective disorder, extroverted personality type). The existence of a depressive syndrome in children is still controversial, but there are investigators who advocate its existence and its protean manifestations (5–8). The question of childhood mania is even more unclear, although efforts are being made to identify either mania or a "manic equivalent" in childhood. For example, there has been some success in the use of lithium to treat episodic behavior disorders in children (9, 10).

This study was undertaken to add to our understanding of bipolar affective disorder in children and

adolescents by examining the natural history of their disorder. It was proposed that the presence of a major psychiatric illness at a time when identity issues are being formulated and resolved might alter the adjustment of these patients and/or the course and prognosis of their illness, i.e., those who become ill during adolescence would have a poorer prognosis than those with later onset, either because the disease is worse or because they are more vulnerable.

METHOD

The diagnosis of bipolar affective disorder, using the criteria of Feighner and associates (11), was made in over 100 patients admitted to the NIH Clinical Center as patients of the National Institute of Mental Health Affective Disorder Study. They had either been admitted with a manic episode or had a manic episode during their Clinical Center hospitalization. The follow-up study of Carlson and associates (12), which ended in 1974, and admissions since then have included 28 patients whose first episode of affective disorder was recorded to have been before age 20. These patients were compared with a population of 20 patients who carried the same diagnosis but whose illness did not begin until after age 45, when they presumably had resolved adolescent identity issues. Age at onset was defined as the age at which the patient or a family member first noted affective symptoms of an intensity or duration that represented a change from the patient's usual personality. This may or may not have been the first time these individuals received treatment for these symptoms.

The two groups were examined using both the extensive admission histories obtained on all patients and the semi-structured personal interviews of patients and spouse or family member that were part of the previously reported follow-up study (12). Data included 1) duration of illness, 2) number and type of episodes, 3) occupational and educational achievement, 4) family history of affective disorder, 5) marital status, and 6) functioning at the time of follow-up. Statistical analysis involved Student's t test and chi-square analysis to compare early- and late-onset groups; Pearson product-moment correlations were used to compare the variables with each other.

RESULTS

Age at onset, duration of illness, sex distribution, and present age are presented in table 1. No statistically significant differences were found between the adolescent-onset and late-onset patients in sex distribution, type of onset (i.e., depression or mania), or distribution of episodes. Furthermore, the mean frequency of episodes per year (total number of episodes divided by duration of illness in years) was about the same for both groups (mean = .40).

Family history of psychiatric illness could be assessed reliably only in first-degree relatives. Histories of psychiatric illness other than affective disorder were negligible in both groups. Although there was no statistically significant difference in the percentage of affected first-degree relatives between the adolescent- and late-onset groups (54% and 35%, respectively), the adolescent group reported more siblings with depression and/or mania and the late-onset group had more affected parents.

Almost half of the early-onset group had never been married, compared with 5% of the late-onset group ($p < .001$). The two groups had similarly high divorce rates.

Outcome was assessed by educational level, income level, and a 4-point rating scale that compared the patient's level of functioning in job or school, social interactions, and family at follow-up with premorbid levels. In this rating system, explained in detail elsewhere (12), 4 is optimum functioning and 1 is poorest functioning. In cases in the adolescent-onset group where current job status could only be compared with prior school performance, we rated academic achievement and ultimate employment at follow-up.

The two groups had comparable educational achievement (≥ 14 years of schooling). The difference

in income (mean = $15,000 in the early-onset group and $25,000 in the late-onset group) is probably secondary to the current age disparity between the two groups. The average function score in both groups on the 4-point overall scale (mean = 2.5 in early onset, 2.3 in late onset) suggests some impairment, but there is no statistically significant difference between the two groups. The distribution of scores was also similar in the two—60% are doing quite well (scores of 4 and 3), 20% are significantly impaired but functioning (score of 2), and 20% are chronically incapacitated (score of 1). As might be expected, more of the late-onset group are dead; 4 of the late-onset group have died (2 suicides), compared with 1 death (from suicide) in the adolescent-onset group. Of the 48 patients, 2 have been lost to follow-up (1 from each group).

DISCUSSION

Recent reports (13, 14) have suggested that age of onset of affective disorder might delineate subgroups of unipolar and bipolar illness, but our findings do not support this. Although one might hypothesize that having a first episode of mania or depression in late childhood or adolescence could predispose patients to a poorer outcome by virtue of their having been afflicted at an earlier and more critical time or having had a longer duration and therefore more episodes of illness, most of our data suggest that early age of onset has little measurable impact on outcome. This is not to say that the adolescent-onset group does universally well, but they do no worse than their older counterparts. Winokur (15) drew the same conclusion in a comparison of patients with onset before the age of 30 with those whose illness onset was after 30.

Although specific follow-up studies on adolescent-onset bipolar affective disorder are not common in the literature, there have been a few that have made a distinction between unipolar and bipolar manic-depressive illness, which makes it possible to compare their findings with ours (16–19). These previous studies had a total of 99 patients between the ages of 12 and 22. Although it was noted that the appearance of the earliest episodes was often atypical, the periodicity of symptoms and eventual resemblance to classical mania and depression allowed the diagnosis of bipolar manic-depressive illness to be made. Criteria for good functioning differed, but approximately half of the patients seemed to be functioning well and about a fourth were chronically disabled at follow-up. These figures agree both with those reported here and with follow-up studies of whole populations of bipolar manic-depressive patients (12, 15).

We found no statistically significant difference in numbers of first-degree relatives with affective disorder in our two groups. Since the siblings and parents of the adolescent-onset group are not past the age of risk for manic-depressive illness, it is possible that there will ultimately be a difference in these groups. Proband reporting of illness in family members is unreliable (20), so corroborating data from family members were obtained where possible. It is conceivable that the late-onset group, who were considerably older, recalled those data less well than the early-onset group.

The income difference between the adolescent- and late-onset groups is probably a result of the 25-year difference in the mean ages of the two groups. Furthermore, the majority of adolescent-onset patients who were counted as having no income were, in fact, still in college.

Educational achievement, which is currently about equal for the two groups, may change as some of the adolescent-onset patients who are still in college and graduate school get their degrees. It is still probable that any difference between the groups could be explained by disparities in age and generation.

We noted that a larger proportion of adolescent- than late-onset patients was single. The 12 single adolescent-onset patients had a mean age of 27.8 years and the 16 married or divorced patients of 41.3 years. Furthermore, of the 9 oldest adolescent-onset patients (current mean age of 50 years), only 1 is still single. Thus it is possible that the unmarried early-onset patients will marry at a later age. There were no statistically significant differences in age of onset, frequency of episodes, education, family history, or general functioning at follow-up between the ever-married and never-married adolescent-onset groups.

The high rate of divorce in both groups suggests the traumatic interpersonal impact of bipolar affective disorder. It seems that the adolescent-onset group is no more at risk for marital dissolution. Moreover, recent data (21) on the divorce rate for a non-psychiatrically-ill population also reveal high lifetime divorce rates (26%).

Prospective studies will be necessary to answer more definitively the question of the impact of affective disorder in the young, since it is difficult to determine retrospectively what might have happened to these people had they not had to contend with this disruptive illness. In his 1952 article on manic-depressive psychosis in children, Campbell (22) noted, "Just as in adults, we observe some manic-depressive individuals who never seem to reach normalcy, others who have distinct but repeated episodes, and still others who have distinct but scattered episodes." It would appear from our data that having the onset of a major affective disorder in adolescence determines neither the severity of the illness nor its course.

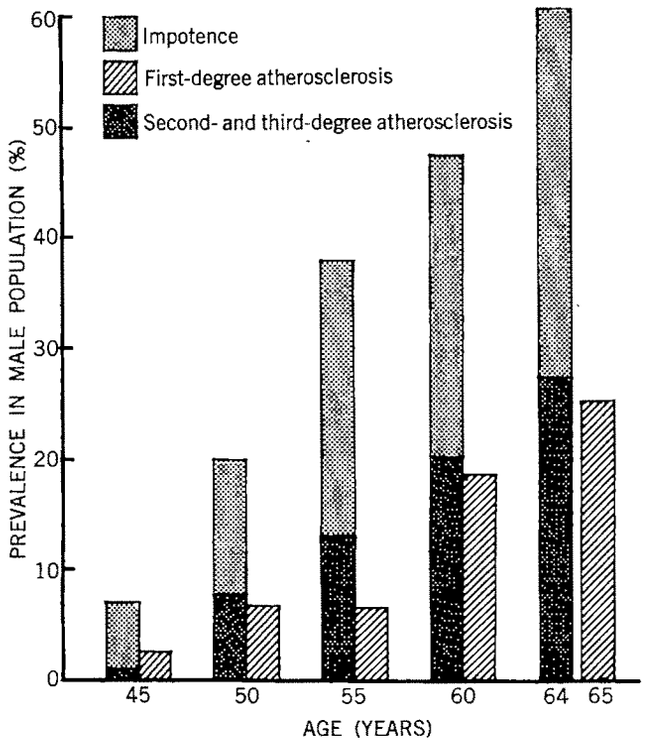
Impotence Responsive to Glyceryl Trinitrate

BY JOHN W. MUDD, M.D.

The author presents suggestive evidence that glyceryl trinitrate served to treat and diagnose atherosclerotic impotence in a man with psychogenic impotence. The prevalence of atherosclerotic impotence is not known but may be relatively high in older men. Vasodilators may be effective in diagnosing these patients, who do not have clear signs of arterial insufficiency of the lower extremities (e.g., Leriche's syndrome). The author postulates a pharmacological interaction between organic nitrates and imipramine.

SEXUAL INTEREST and activity during the middle and older years has been shown to decline (1–3) but nevertheless remains in those who enjoy good general health and the availability of a conjugal partner (1, 4, 5). The hormonal changes noted in aging men may contribute to their attenuated sexual physiological response (5, 6), but they do not cause impotence (5).

Few epidemiological studies of impotence appear in the literature. Kinsey and associates (7) reported an increase in the prevalence rate of impotence from 6.7% in 55-year-old white men to 27% in those 70 years old. Pfeiffer and associates (2) showed that 15% of 123 volunteers 60 years or over developed impotence during a 9-year prospective study period.



The reason for the apparent decline in potency with advancing age is as yet unknown. Of the many organic diseases associated with impotence or known to cause it (4, 8, 9), atherosclerotic vascular disease in particular has been suspected of a major causal role in aging men (10).

In addition to the syndrome described by Leriche and Morel (11), which includes impotence, claudication, absence of femoral pulses, and other signs of vascular insufficiency, other studies of surgical patients (12, 13) indicate that impotence often accompanies symptoms of pelvic arterial obliterative disease with or without diminished femoral pulsations.

It is well known that the prevalence of atherosclerosis increases with age (14). Schilling and asso-

Dr. Mudd was Instructor in Psychiatry, Columbia University College of Physicians and Surgeons, and Assistant Attending Physician, Columbia Presbyterian Medical Center, New York, N.Y. He is currently Assistant Professor in Psychiatry, University of California, San Francisco Medical Center, and is in private practice in San Francisco, Calif. Address reprint requests to 390 Laurel St., San Francisco, Calif. 94118.

FIGURE 1
Prevalence Rates for Iliac Atherosclerosis (15) and Impotence (7) in Older Men

ciates (15) reported the prevalence of first- (0–20 mm of continuous calcification), second- (21–80 mm calcification over one or several sites), and third- (greater than 80 mm calcification) degree iliac atherosclerosis found in radiographic studies of 2,663 white men. Their rates are compared with those for impotence reported by Kinsey and associates (7) (see figure 1). The similar rates of increase of second- and third-degree atherosclerosis and impotence are striking and suggest that atherosclerosis may play an important role in impotence in aging men. The similar prevalence rates of iliac calcifications in excess of 20 mm and impotence further suggests that this degree of atherosclerotic disease may be necessary to cause impotence. Unfortunately, Schilling and associates did not report potency data.

The treatments of impotence are as varied as the historical periods in which they were applied (16). In my search of the literature, however, I failed to discover a report of the use of organic nitrates for erectile failure. Nevertheless, I found unpublished accounts of folk use of amyl nitrite "poppers" by sailors and others "to improve erections," which further encouraged me to report the following case.

CASE REPORT

A 56-year-old Cuban father of two was first hospitalized in 1968 for involutional melancholia. Related psychopathology included impotence, hypesthesias of the arms and legs, dread of cancer and heart attack, episodic alcohol abuse, preoccupation with homosexual fantasies, and a premorbid passive-dependent personality. During the previous 4 years he had experienced frequent partial or complete erectile failure lasting 1–3 months and premature ejaculation associated with marital quarrels and dyspareunia of his wife. At other times he performed "like a 15-year-old."

Although he was generally well and worked as a stock clerk during the next 7 years, he had several brief psychotic depressions precipitated by, for example, the death of his mother or the threatened loss of disability benefits (he later developed a compensation neurosis). He was evaluated four times during this period for intermittent impotence without loss of erection upon waking. Suspected prostatitis with epididymitis and scrotal cellulitis were each diagnosed once and treated with erythromycin. Serum testosterone, spine films, and neurological and peripheral vascular examinations were normal. Psychogenic impotence responsive to continuing psychotherapy was the primary and consistent impression. In psychotherapy the emergence of aggressive fantasies toward his wife commonly alleviated his symptom. He was also evaluated for variable complaints of chest pain, which were not related to sexual activity.

In 1973 he was hospitalized at Columbia Presbyterian Medical Center for heat stroke with impairment of hepatic and renal function and myoglobinemia complicated by pneumonia, *E. coli* septicemia, and an undiagnosed mild left peroneal neuropathy. He received kanamycin, ampicillin, and tetracycline. Of his liver function studies, his alkaline phosphatase, lactate dehydrogenase, and serum glutamic oxaloacetic transaminase have remained borderline or mildly elevated. His ECG showed right bundle branch block at discharge.

During the next 2½ years he was impotent in spite of sexual interest. He failed to note a full erection even on waking, and he was unable to have intercourse. He once complained of diminished sensation, temperature, and size of his penis, and of some urinary dribbling (which he attributed to "poor circulation"). Regular urological examinations were normal or showed recurrent scrotal cellulitis or questionable epididymitis. Follow-up neurological examinations showed no evidence of a progressive neuropathy and a fluctuating sensory examination, which could not be explained neuroanatomically. The additional diagnosis of hysterical conversion neurosis was considered.

He also complained of occasional calf pain or cramps. There was no history of gluteal claudication. Vascular examination of the lower extremities failed to disclose trophic changes, bruits, or diminished pulses or temperature. In addition, he complained of a variety of chest pains in several locations not typical of angina. They were diagnosed as musculoskeletal or pleuritic in origin, with hysterical painful elaboration. At no time in psychotherapy did he fear or give evidence

of unconscious fear that sexual activity could aggravate the heart disease he suspected (17). His fear of heart attack was attributed to his hypochondriacal neurosis.

The patient was again hospitalized in January 1976 for depression precipitated by the threat of divorce by his wife. Although his mood soon normalized in response to his wife's reconsideration, he volunteered for a research trial of 250 mg of imipramine and 15 mg of flurazepam daily. After 8 weeks with serum imipramine levels of 190–200 ng/100 ml, the researchers concluded that these drugs, like other psychotropics in the past, had no important clinical effect on him. At the end of the hospitalization, while the patient was still taking imipramine and flurazepam, one cardiologist initiated a trial on .3 mg of glyceryl trinitrate (GT) sublingually in response to complaints of chest pain.

The patient reported that the nitrate relieved a particular substernal chest pain and any leg pain (but not cramps) within seconds. He has continued to take one to four tablets daily. A presumptive diagnosis of angina pectoris with intermittent claudications was made. Laboratory stress and 24-hour ECG monitoring disclosed no abnormality. His fasting cholesterol was normal; his triglycerides were elevated between 335 and 473 mg/100 ml. With exercise (pulse 166–120) a loud flow murmur was heard over the lower abdomen transmitted to his femoral arteries. His peripheral pulses remained full.

Two days after initiating the nitrate and 6 hours after a .3-mg application, he was surprised to be awakened by his first erection in 2½ years. He subsequently reported that within seconds of taking the nitrate, his penis became partially or fully erect for perhaps 10 minutes (he did not experience an enhanced sense of libido or well-being) and that waking erections, some of which were unusually painful, occurred three to four times a week. He masturbated and achieved intercourse with orgasm.

One week later he began taking 5 mg of pentaerythritol tetranitrate (PT) four times daily. He spontaneously reported that within 30 to 45 minutes of ingestion of this medicine, his penis regained its normal size and sensitivity. He noted that the effect persisted as long as he took the medicine in four doses daily.

His potency response did not change when he reduced his cigarette consumption to one package daily or discontinued the imipramine 3 weeks after beginning PT therapy. Concurrently with discontinuance of imipramine he was given trimethaprim and sulfamethoxazol (Septra); he is now taking erythromycin for recurrent painful prostatitis and seminal vasiculitis, which has inhibited his ejaculations. Hemogram, erythrocyte sedimentation rate, Venereal Disease Research Laboratories test, serum B_{12}, 9-hour postprandial glucose, acid phosphatase, urinalysis, intravenous pyelogram, and cystoscopy were normal.

A delayed diagnosis of atherosclerotic impotence in addition to psychogenic impotence was made.

DISCUSSION

The reported temporal association of nitrate ingestion with changes in penile volume, temperature, and sensation, and relief of chest and leg pain strongly suggests a vasodilatory effect of nitrates on this man's pelvic circulation. The appearance of a lower abdominal bruit during high cardiac output strengthens the suspicion that he has atherosclerotic disease of his coronary and peripheral arterial circulation. The failure to note typical ECG changes during the stress study could indicate, as demonstrated arteriographically in some patients with variant angina, that he has predominately arteriospastic disease of the coronaries that is not typically aggravated by exercise (18). Probable claudications with a normal peripheral examination also suggest primarily spastic, in contrast to obliterative, disease in his distal circulation. Similar pathology is likely to be present in his internal iliac system. It is probable that this man's hypertriglyceridemia heightened his risk for atherosclerosis (19).

GT and PT are known to vasodilate a number of visceral (20) and peripheral (21, 22) arteries by relaxing smooth muscle. It seems likely that the internal iliac and pudendal circulation (the integrity of which with parasympathetic innervation is primarily responsible for potency [23]) is similarly influenced by nitrates.

In this case the time interval of several seconds between the patient's application of GT and the reduction of chest and leg pain and the onset of his erections is commensurate with current pharmacological knowledge of the serum dynamics of GT (21, 24, 25). The patient's interpretation of the effects of oral PT, i.e., that its clinical onset occurs in 30–45 minutes and lasts several hours, may also be accurate in his case. However, this length of action of PT has been questioned (26).

The patient's waking erection 6 hours after applying .3 mg of GT sublingually before starting PT is unexplained. Most likely the patient's suspected arteriosclerotic/spastic condition is such that segmental spasms occur only infrequently but last a long time. This formulation is compatible with his inconsistent symptoms of vascular insufficiency. Once the spasm is relieved by GT, the vessels remain without stenosis for several hours and permit normal nocturnal autonomic stimulation of his erection. Other hypotheses (27, 28) can be argued, but one that may also explain the long-lasting effect of PT is particularly interesting.

Denitration is enzymatically mediated by glutathione reductase, and depletion of glutathione (substrate) may greatly slow the inactivation of the organic nitrates (20). During the first month of nitrate treatment the patient was receiving imipramine. It has been recently shown that during the degradation of imipramine to 2-hydroxyimipramine an epoxide intermediary may be formed which transiently but strongly binds glutathione (29). According to a personal communica-

tion from Dr. J. Perel, New York State Psychiatric Institute, this postulated metabolic step of imipramine may have trapped hepatic glutathione to such a degree as to explain a 6-hour action of GT.

This patient's apparent response to nitrates may be idiosyncratic or peculiar to an altered metabolic capacity. However, further research may reveal nitrates or other vasodilators effective in diagnosing and treating atherosclerotic impotence whether or not clinically evident or shown by arteriography, Doppler flow, or plethysmographic penile studies.

The prevalence and specific causes of impotence also need to be determined in a large representative sample of aging men. This information will help psychiatrists who are continually challenged to differentiate organic from psychogenic impotence.

Lack of Effect of Naloxone on Schizophrenic Symptoms

BY DAVID S. JANOWSKY, M.D., DAVID S. SEGAL, PH.D., FLOYD BLOOM, M.D., ALAN ABRAMS, M.D., AND ROGER GUILLEMIN, M.D., PH.D.

Several lines of evidence suggest that naloxone (*N*-allylnoroxymorphone), commonly used as a narcotic antagonist, may have antipsychotic properties. Like other substances with proven antipsychotic properties, naloxone is reported to inhibit apomorphine-induced stereotyped behavior in the rat (1). Naloxone and chlorpromazine, given together, enhance each other's rate-decreasing effects on schedule-controlled behavior in the pigeon (2), which also suggests that naloxone has neuroleptic-like behavioral effects. In addition, naloxone inhibits *d*-amphetamine-induced increases in locomotor activity in the rat (3), although in recent unpublished studies we have found that naloxone pretreatment does not diminish, and in fact may enhance, *d*-amphetamine- and methylphenidate-induced stereotyped behaviors in the rat.

In regard to schizophrenic disorders, Bloom and associates (4) have reported that β-endorphin induces a "catatonic like state" in rats that they described as "reminiscent of some aspects of schizophrenia." Further, they reported that naloxone immediately antagonized this and other actions of β-endorphin. Bloom and associates proposed that administration of opiate antagonists such as naloxone might be expected to modify the clinical status of some psychiatric patients if altered β-endorphin function were involved in the etiology of their illness. More significantly, Gunne and associates (5), in a single-blind pilot study, reported that I.V. naloxone in doses of .4 mg rapidly and selectively abolished auditory hallucinations in four chronic schizophrenics.

Dr. Janowsky is Professor and Dr. Segal is Associate Professor, Department of Psychiatry, University of California, San Diego, School of Medicine, P.O. Box 109, La Jolla, Calif. 92037. Dr. Bloom is Director, A.V. Davis Center, Salk Institute, La Jolla, Calif., where Dr. Guillemin is Director, Neuroendocrinology Laboratory. Dr. Abrams is Psychopharmacology Research Fellow, Veterans Administration Hospital, San Diego, Calif.

This work was supported by Veterans Administration grant MRIS-4576 from the Medical Research Service and by Alcohol, Drug Abuse, and Mental Health Administration grant DA-01568-01 from the National Institute of Drug Abuse.

Method

The subjects were eight male schizophrenic patients (three paranoid, three schizo-affective, and two chronic undifferentiated) ranging in age from 19–48 years (mean=30), all of whom were receiving antipsychotic drugs (fluphenazine in doses of 10, 40, 80, and 100 mg/day, respectively; chlorpromazine, 300 and 600 mg/day, respectively; haloperidol, 50 mg/day; and trifluoperazine, 30 mg/day). All gave fully informed consent to participate in the study of naloxone's effects on hallucinations and other schizophrenic symptoms. The diagnosis of schizophrenia was based on *DSM-II* (6) classifications and the presence of Schneider's first-rank symptoms (7). All patients were grossly psychotic and could be considered process schizophrenics. Six patients were having active auditory hallucinations at the time of the experiment.

In a double-blind crossover design with counterbalanced order of administration, 1.2 mg of I.V. naloxone was rapidly given; saline placebo was given either 24 hours before or 24 hours after naloxone. Each patient was interviewed by a psychiatrist for a period beginning 15 minutes before and ending 60 minutes after each I.V. infusion. The psychiatrist rated the patients at 15-minute intervals using the Brief Psychiatric Rating Scale (BPRS) and asked them to describe any psychological or physical effects.

Results

Analysis of variance of individual BPRS items and total BPRS scores revealed no significant or nearly sig-

nificant differences between placebo and active naloxone. Specifically, no significant changes occurred in the following BPRS items indicative of schizophrenia: hallucinations, conceptual disorganization, unusual thoughts, mannerisms, grandiosity, blunted affect, and depression. None of the patients reported a decrease in auditory hallucinations. Two patients said they felt less nervous after naloxone infusion compared with one after placebo infusion, and two felt drowsy after naloxone infusion compared with one after placebo. No other mood changes were noted.

Discussion

We have not been able to confirm the report of Gunne and associates that naloxone has antihallucinogenic properties (5). It is significant that our patients, like those of Gunne and associates, were receiving neuroleptics and were severely and chronically ill. Thus in our eight subjects naloxone does not seem to have immediate antipsychotic and antihallucinatory effects when administered in I.V. doses of 1.2 mg. However, it should be mentioned that our results do not preclude the possibility that 1) higher and/or more chronic doses of naloxone might have antipsychotic effects, 2) naloxone may ameliorate symptoms in other subgroups of psychotic patients, or 3) naloxone may relieve psychotic symptoms in schizophrenics who are not receiving neuroleptics.

Low Levels of Dopamine β-Hydroxylase and Psychosis

BY JOHN A. EWING, M.D., ROBERT A. MUELLER, M.D., PH.D., BEATRICE A. ROUSE, M. ED., AND DAVID SILVER, M.D.

Disulfiram (Antabuse) is known to be an inhibitor of dopamine β-hydroxylase (DBH) and has been used for this purpose in animal research (1). It is currently hypothesized that the presence of excessive amounts of dopamine within the mesolimbic system is involved in schizophrenia (2); therefore, it seems possible that disulfiram could provoke a psychosis by blocking the production of norepinephrine from dopamine. This would presumably be more likely to occur in persons whose supply of DBH is already minimal or borderline. Heath and associates (3) showed that larger than normal doses of disulfiram (1–1.5 g/day) led to an increase in psychotic symptoms in schizophrenia.

We have recently seen a case of psychosis in the course of a double-blind study of disulfiram that sheds some light on these issues. The full study will be described elsewhere; its purpose was to compare side effects of disulfiram with placebo in healthy males and to measure levels of plasma DBH for evidence of possible inhibition. All subjects took disulfiram in dosages of 500 mg/day for 1 week and 250 mg/day for the next 2 weeks within the total 9-week observation period.

Case Report

During the study described above, 1 of our 30 subjects had a psychotic reaction. All subjects provided a health history before admission to the study, but this subject had lied to us about his psychiatric history. When he was 25, he had had an illness diagnosed as schizophrenia (slightly more than 1 year before the study). Treatment had been recommended at that time, but he refused. The episode that occurred while he was in our study began after he had been on disulfiram for 3 weeks and then on placebo for 8 days. He

This study was supported by the University of North Carolina at Chapel Hill Center for Alcohol Studies, by North Carolina Alcoholism Research Authority grant 7406 to Robert A. Mueller, and by a grant from Ayerst Laboratories to the Center for Alcohol Studies.

The authors wish to thank Kenneth Jobson, M.D., for access to his clinical notes on the care of the patient described in this paper.

failed to report for one of his thrice-weekly evaluations and was incoherent when we reached him by telephone. A home visit was made, and he was then seen in the hospital emergency room and admitted to the psychiatric service. His girl friend, who lived with him, told us that she had noticed him acting in a peculiar manner for 3 or 4 days previously.

The notes of the treating psychiatrist state that the patient had been observed speaking to people who were not present, mumbling, withdrawing socially, and posturing in a catatonic manner. He made irrational statements, responded better to female than to male personnel, and showed severe looseness of association and blunting of affect. At times he grimaced and smiled inappropriately and would not explain why. There was a paranoid flavor to some of his ideas; he reported a feeling of vague uneasiness and felt that some undefined force was against him.

There was some improvement after treatment with antipsychotic drugs, but since he had been assaultive on two occasions, the psychiatrist sought to have him committed for a longer stay in the hospital. An examining judge refused to sign commitment papers and the patient was able to leave the hospital against medical advice. Full neurological studies, including EEGs, had revealed no evidence of organicity and the final diagnosis was schizophrenia. We have learned from his girl friend that there is no reason to suspect that his psychosis was induced by hallucinogenic drugs and that he has now returned to his premorbid personality. Both she and the patient's father stated that this episode was exactly like the one that had occurred a year earlier.

All subjects in this study were seen three times each week for evaluation and for venipuncture so that DBH levels could be estimated. When the code was broken and the results were scrutinized, we discovered that this subject had a markedly lower blood DBH level than the other subjects. Results are expressed as nanomoles of octopamine per milligram plasma protein per hour; the methodology has been described previously (4). This subject's initial blood sample showed no detectable DBH activity. The mean DBH value for the other 29 subjects on the first day of the study was 28.2 nmol/mg (SD=18.7). Fourteen blood samples were taken before this subject dropped out of the study—the mean for all 14 was 1.28±0.80 nmol/mg. Thus, this patient's DBH activity was consistently lower than that of all the other subjects, who had values ranging from 2.11 to 75.0. There was no sudden change in DBH values at the time of the onset of psychosis.

Discussion

DBH does not cross the blood-brain barrier, and the levels found in peripheral plasma are believed to come primarily from the sympathetic nervous system (5). If peripheral blood levels of DBH correlate positively with brain levels, it might be that this subject was more easily thrust into a state of psychotic decompensation because of the low reserves of DBH in his central nervous system. Under these circumstances the administration of a DBH inhibitor such as disulfiram would be likely to produce a build-up of dopamine and a relative excess of dopamine to norepinephrine in parts of the central nervous system.

Other workers have found no consistent relationship between peripheral DBH levels and psychiatric syndromes (6). At one time it appeared that DBH levels in human brain were significantly lower in schizophrenics than in normal subjects (7), but this finding has not been corroborated (8). Peripheral blood levels of DBH remained consistent within each individual throughout this 9-week study, and we were not able to demonstrate peripheral DBH inhibition by disulfiram. However, this case is interesting because it correlates with the earlier report of Heath and associates (3) and indicates that this patient, by having less reserves of DBH, may have been more at risk for a psychotic state.

Secondary Mania? A Case Report

BY KENNETH N. WIESERT, M.D., AND HUGH C. HENDRIE, M.D., CH.B.

The concept of affective disorder occurring as a secondary phenomenon in the course of other illnesses is now well established. With few exceptions, however, the syndrome described is that of depression. Although elevation of mood occurs in association with various drug therapies and manic symptoms have been described in the postencephalitic syndrome (1), case reports of the complete syndrome of secondary mania are rare, and one group of investigators has expressed doubt that it exists (2). However, over the past 4 years there have been three reports of apparent mania occurring in association with other illnesses (3–5). The establishment of the category of secondary mania has considerable diagnostic, etiological, and treatment significance, and it is important to document cases as they occur. The purpose of this paper is to report one such case.

Case Report

In September 1975, a 57-year-old woman was admitted to the medical ward of the Indiana University Hospital with a 5-day history of progressive headaches and drowsiness. At the time of admission she was confused and had a temperature of 104° F, but the rest of the examination was essentially normal. Her history revealed a diagnosis of chronic lymphatic leukemia 4½ years earlier; the disease was subsequently considered to be in remission. An EEG, brain scan, echoencephalogram, and cerebral anteriogram were all normal. Serial lumbar punctures were performed. The modal examination revealed 50–60 leukocytes, no erythrocytes, 100 mg/100 ml of glucose and 30/100 ml of protein. A diagnosis of encephalitis was made and the patient was given a course of cephalothin sodium and tobramycin. She remained lethargic and drowsy for the first 3 weeks of hospitalization and continued to spike high temperatures. She then showed progressive improvement and was discharged on no medication 5 weeks after admission, at which time her mental status was reported to be approaching normality, with the exception of minor memory impairment. Convalescent titres for St. Louis Type arborvirus were positive at 1:32 dilution. The discharge diagnosis was St. Louis Type A encephalitis. At home, she quickly returned to normal physically and mentally and was reported to be healthy on follow-up examination.

She continued to function well until the end of May 1976, when, according to her husband, she underwent a change in behavior. She became increasingly hyperactive, developed pressured speech, and had marked insomnia. She exhibited increasingly poor judgment and became quite grandiose and argumentative with no obvious psychosocial precipitant. There was no history of psychiatric disturbance; she had been a very conscientious, cautious woman. She was admitted to the psychiatric unit in August 1976 on a temporary hold order.

On admission she was quite hyperactive and had pressured speech. Her affect fluctuated from mild euphoria to anger. Her gross intellectual functions appeared normal, as did her orientation and memory. Physical and neurological examinations were normal. Laboratory investigations, including cerebrospinal fluid examinations and EEG, were all essentially within normal limits. A neuropsychological evaluation revealed minor difficulties with complex problem solving. Although a thorough family history revealed no evidence of psychiatric disturbance, a tentative diagnosis of mania was made. She was started on haloperidol, 4 mg b.i.d., which decreased her hyperactivity. However, she remained irritable and continued to have difficulty sleeping. The third week after admission, she was given a weekend pass and was argumentative and impulsive at home. When she returned to the hospital, lithium therapy was started at a dose of 300 mg t.i.d. and haloperidol was discontinued. She quickly attained and maintained a serum lithium level of 0.7–0.8 mEq/liter. Her hyperactivity improved, her sleeping pattern returned to normal, and her mood stabilized. She was discharged 5 weeks after admission with a diagnosis of mania. Since that time she has been seen monthly and has remained on lithium. She continues to perform well and is normoactive and euthymic 3 months after discharge.

Discussion

We believe the diagnosis of mania was justifiable in this patient. She fulfilled the criteria for that diagnosis, with the obvious exception of a previous neurological illness, and responded well to lithium. The relationship of the manic symptoms to her prior encephalitis is less certain, but we believe it is a reasonable assumption given that the patient had no history of major psychiatric disturbance, an onset at the age of 58, and no family history of affective disorder. In addition, although her intellectual functions were intact on mental status examination, a minor deficit in cognitive function was found during neuropsychological evaluation, which is consistent with a mild static cerebral disorder.

There is a marked similarity between the clinical picture of this patient and that of the patient previously

Dr. Wiesert is Chief Resident, Department of Psychiatry, Indiana University School of Medicine, 1100 West Michigan St., Indianapolis, Ind. 46202, where Dr. Hendrie is Professor and Chairman. Address reprint requests to Dr. Hendrie.

described by Rosenbaum (5). Both patients had histories of cerebral insult followed by a period of several months during which they performed well; then both developed manic symptoms. Clinical mental status examination in both patients revealed little evidence of organicity, and both patients responded to lithium.

It is difficult to establish the number of cases of mania occurring in association with other illnesses that would be necessary to justify a category of secondary disorder. However, given this case and the previously reported cases, it seems that this category is at least a possibility. Thus, the syndrome of mania, like that of depression and schizophrenia, could represent a final common pathway with multiple etiologies and could be subclassified into primary and secondary components.

Anger Arousal by a Motion Picture: A Methodological Note

BY WALTER ARMIN BROWN, M.D., DONALD P. CORRIVEAU, M.A., AND PETER M. MONTI, PH.D.

Although anger and its regulation are thought to play a crucial role in healthy and pathological personality development, interpersonal relations, "psychosomatic" illness, and criminal violence, there has been little systematic research on the physiology of anger or the psychological variables involved in its regulation and display (1). This dearth of systematic inquiry results in part from the lack of a laboratory model for eliciting and observing anger in a controlled, systematic, and ethical fashion.

Previous laboratory studies have used harassment of subjects or frustrating tasks to provoke anger (2). These procedures involve deception and have serious methodological as well as ethical flaws (3). Films with threatening and erotic content have been shown to reliably evoke anxiety and sexual arousal in laboratory settings (4) but have not, to our knowledge, been used to evoke and study anger in a laboratory setting. We now report the results of a preliminary study in which we showed that a film evoked specific and significant anger. These findings suggest a potential research tool for the study of anger and may provide information regarding stimuli for anger provocation.

Method

The subjects were 36 undergraduate men (N=14) and women (N=22) aged 18–31. They were randomly assigned to view one of two 20-minute made-for-television Alfred Hitchcock films or two 10-minute documentary films. The first Hitchcock film, "Man from the South," involves a wager in which the protagonist could have a finger chopped off and has been shown in previous psychophysiological research to regularly evoke subjective anxiety and its physiological concomitants (4, 5). The second Hitchcock film, "The Crooked Road," is the story of a couple taking an automobile trip who are unfairly accused of breaking the speed limit, mistreated by the police and judge, and coerced and cheated by the local service station. We hypothesized that this film would evoke anger on the basis of its content, our own reactions to it, and the response of laboratory personnel who saw it. The documentary films we used have been shown to evoke no changes in reported psychological state, autonomic nervous system, or endocrine variables (4).

There were no differences in age or sex distribution among the subjects in the three film groups. All films were shown at midmorning on the same day. Subjects were told that we were interested in the effect of films on mood and were asked to complete the Profile of Mood States (POMS) immediately before and after the films (6). The POMS, a widely used mood assessment instrument, is composed of 65 mood adjectives rated on a 5-point scale and scored for 6 mood factors. This test has been shown to be sensitive to transient changes in mood including mood changes evoked by films with threatening content (6).

Results

A 3 × 2 repeated-measures analysis of variance was carried out on the mean pre- and postfilm POMS scores (see table 1). Significant interactions between

The authors are with the Providence Veterans Administration Hospital, Davis Park, Providence, R.I. 02908, where Dr. Brown is Director, Neuroendocrine Research Laboratory, Mr. Corriveau is Research Psychologist, and Dr. Monti is Director, Day Hospital. Depression	5.3	6.1	7.0	6.6	3.9	3.3
Anger**	2.8	9.7	4.1	6.6	3.3	2.6
Vigor***	15.5	11.3	16.4	14.6	17.0	14.8
Fatigue‡	7.7	6.1	5.3	5.2	6.9	5.8
Confusion	6.2	6.3	7.2	7.3	5.7	5.0

*$p<.001$, analyses of variance, Trials×Conditions interaction.
**$p<.01$, analyses of variance, Trials×Conditions interaction.
***$p<.001$, analyses of variance, trials effect only.
‡$p<.05$, analyses of variance, trials effect only.

changes in mood and type of film were found only for anger ($F=5.40$, $p<.01$) and tension ($F=8.78$, $p<.001$). Further analyses for simple effects reveal anger to be increased significantly only after "The Crooked Road" ($p<.001$), with no significant change in anger after the other films. Tension was increased significantly ($p<.001$) only after "Man from the South." All films were associated with decreases in fatigue ($F=4.62$, $p<.05$) and vigor ($F=13.2$, $p<.001$), with no differences among films on these dimensions (trials effect only). Depression and confusion scores did not change following any film condition. Baseline POMS scores did not vary among the film groups and were consistent with reported normative POMS data from college populations (6).

Discussion

Our study revealed an unexpectedly significant and specific increase in reported anger following a film. These findings, if replicated with larger and more diverse groups, would suggest a role for selected films as research instruments in multifaceted studies of anger and aggressive behavior. In attempting to understand the relative potency of the experimental film in evoking anger, the possibility that the demand characteristics of the situation influence reported mood must be taken into account. Further research with these and other films using varied populations, changes in instructional set, and physiological measures will be necessary to clarify the influence of the demand variable on reported mood change. Feshbach (3) pointed out that "violations to self-esteem through insult, humiliation, or coercion are powerful elicitors of hostility, probably the most important source of anger and aggressive drive in humans." "The Crooked Road" depicts a series of insulting, humiliating, and coercive experiences in a way that seems to facilitate identification with the victim. This type of vicarious experience may be sufficiently powerful to elicit a degree of anger measurable on both subjective and physiological dimensions. Differences in response to such a film may be related to a variety of historical, personality, and physiological variables. Identification of the correlates and predictors of differential response to a potentially anger-evoking film may provide a step toward understanding the role of anger and its regulation in personality development, illness, and violence.

Methadone Maintenance in a Patient on Chronic Hemodialysis

BY WILLIAM M. GLAZER, M.D., AND GEORGE L. COHN, M.D.

In this paper, we will report the case of a patient who is on chronic dialysis and who has been seen regularly by the consultation-liaison psychiatrist on the dialysis unit (W.M.G.). This patient illustrates interesting points about patients on chronic hemodialysis who are also addicted to narcotics.

Dr. Glazer is a fourth-year resident, Department of Psychiatry, Yale University, Mental Hygiene Division, Yale Health Plan. Dr. Cohn is Associate Clinical Professor, Department of Psychiatry and Medicine, Yale University School of Medicine, New Haven, Conn., and Chief, Consultation-Liaison Psychiatry, West Haven Veterans Administration Hospital, Spring St., West Haven, Conn. 06516. Address reprint requests to Dr. Cohn.

Case Report

The patient is a 56-year-old man who has been on chronic hemodialysis for the past year because of renal failure secondary to recurrent renal calculi of 25 years' duration. Because of his illness, he was unemployed

for 25 years and lived at home with his wife and four children, supported by Social Security benefits. The deterioration of his renal function resulted in hemodialysis beginning in February 1975. In addition to his renal failure, the patient has been addicted to morphine for the past 20 years; he feels that this addiction is iatrogenic secondary to narcotics given to him for renal colic. Over the past 5 years he has been a methadone maintenance patient in a nearby drug dependence unit.

For much of his 6 months in the hemodialysis unit the patient was a difficult management problem—he would become agitated and make derogatory and embarrassing remarks to the nursing staff and on occasion pulled out his needles and walked off the unit. This disruptive behavior occurred at least once a week during the course of his thrice-weekly 5-hour dialysis treatments. The disruptive state was not improved by administration of diazepam, haloperidol, or nonnarcotic analgesics.

The other medications the patient received were routine. Laboratory values were in the range to be expected for patients with chronic renal failure. Mental status examination revealed no psychosis or evidence of an organic brain syndrome.

The liaison psychiatrist was requested to see the patient in September 1975 because of a recent suicide attempt. The patient talked about not wanting to live and admitted to two suicide attempts in the preceding month. He said that he was upset because his wife and family had been ignoring him recently and were threatening to send him to a nursing home. The hemodialysis unit staff offered the information that one of his sons had recently married and left home. The patient felt that his disruptive behavior on the hemodialysis unit resulted from pain at the site of his fistula. He was hospitalized on a brief-treatment psychiatry unit because of his suicidal ideation, and his thoughts of suicide ceased during the hospitalization. The staff explored his family situation and noted severe communication problems.

One week after discharge, the disruptive behavior recurred. The psychiatrist believed that most therapeutic approaches had been exhausted and arranged a meeting between the staffs of the hemodialysis and drug dependence units in the hope that they could share information that would lead to a solution of the problem. It was learned that the drug dependence unit had been delivering methadone to the patient's home 3 days a week on nondialysis days; these deliveries always contained the next day's methadone supply. The staff speculated that the patient's difficult behavior during dialysis might be understood as a psychological withdrawal—the patient was taking the methadone meant for dialysis days on the preceding day, and therefore had no methadone on the days when he was dialyzed.

The patient was instructed to bring his methadone to the dialysis unit; a member of the dialysis staff administered the drug. Once this plan was initiated, the patient's difficult behavior ceased and he developed a good relationship with the staff that continues at this writing.

In patients with complicated medical problems who require chronic care from several disciplines, it is essential to have good communication between the systems involved. In the case we have described sharing of information resulted in a solution to a problem that had not been solved by the usual approach (1), in which attention is focused on the patient, the staff, or both. Several authors (2, 3) have spoken of the importance of paying attention to systems beyond the boundaries of the one in which the patient is being treated.

Since the passage of new legislation that entitles anyone, including those with severe psychiatric disorders and drug or alcohol addiction, to receive hemodialysis maintenance, psychiatrists working with hemodialysis units have been faced with difficult diagnostic and management problems. It is hoped that the presentation of this case will remind the psychiatrist of the importance of considering forces affecting the patient that arise outside the system in which he is being treated.

Lithium-Induced Aggravation of Tardive Dyskinesia

BY EUGENE L. CREWS, M.D., AND ARTHUR E. CARPENTER, M.D.

There is a strong association between tardive dyskinesia and the use of neuroleptic drugs (1), and signs of pseudo-parkinsonism may persist long after discontinuation of neuroleptics (2). Observers have also been finding some association between lithium treatment and pseudo-parkinsonism symptoms (3, 4). In nontoxic patients lithium is known to produce a fine tremor that may become coarse with development of muscle twitching in intoxication (5). There has been little written about lithium and tardive dyskinesia, although one paper suggested that lithium might be of benefit in the treatment of this syndrome (6). In this report we will describe a patient in whom lithium carbonate seemed to aggravate substantially a preexisting tardive dyskinesia.

Case Report

The patient, a 46-year-old woman, was admitted to the hospital in a state of irritable excitement. This was her fourth psychiatric admission since the age of 27. She had been taking trifluoperazine and benztropine mesylate, which were stopped 1 week before her admission. Her mood was expansive and her affect was labile. She had pressured speech and flight of ideas and was diagnosed as having bipolar affective disorder, manic phase. Neurological exam revealed an oral dyskinesia, repetitive purposeless turning of the head (to the left more than the right), and continuous athetoid movements of the fingers of both hands (left more than right). These movements, which the patient said began about 5 months previously, were diagnosed as a tardive dyskinesia. Family history, clinical picture, and computerized axial tomography did not support a diagnosis of Huntington's chorea.

Lithium carbonate, 300 mg q.i.d. per os, was started on the 2nd hospital day. There were no other medications. On the 9th day the hyperactivity, irritability, and rapid speech had cleared partially. The serum lithium level was 2.02 mEq/liter. On the 12th day the patient developed massive, continuous choreoathetosis of fingers, hands, arms, head, and jaw, and "fly-catcher" tongue. There was no vomiting, weakness, muscle twitching, or impairment of consciousness, but she had difficulty speaking and swallowing. The lithium level was 2.18 mEq/liter. No lithium carbonate was given for the next 48 hours. The choreoathetoid movements returned almost to the admission level by the 14th day.

Lithium carbonate was resumed at 300 mg t.i.d., and deanol, 100 mg t.i.d., was started. After 1 day the movements began to increase in severity. The serum lithium level was 1.72 mEq/liter. The lithium carbonate dosage was decreased to 300 mg b.i.d. By the 20th hospital day, the movements were less severe than they had been at admission and at times were almost absent; the serum lithium level was 1.11 mEq/liter. The patient's mood was euthymic.

Discussion

The abrupt worsening of this woman's tardive dyskinesia may have been a progressive and continuing unblocking phenomenon that began after the phenothiazine was discontinued a week before this admission. The lithium treatment then would have been a coincidental and noncausal factor. However, the abruptness of the worsening over the course of 4 hours on the 12th hospital day in association with a lithium level of 2.18 mEq/liter is suggestive of a relationship. This possibility is strengthened by the marked diminution of the movements after lithium was discontinued. When lithium was resumed, albeit in a decreased dosage and concurrently with administration of deanol, the movements began to worsen again. The movement disorder again improved substantially with a decrease in the lithium dosage and continued administration of deanol.

The course of events in this case indicates that lithium toxicity may be expressed as an aggravation of a tardive dyskinesia. This patient tolerated lithium without exaggeration of her movement disorder before a high serum level was reached. Eventually, the severity of her abnormal movements was less at a therapeutic lithium level than it was when she was admitted. It is difficult to estimate the contribution of deanol to the final clinical state; lithium and deanol may be synergistic in the treatment of tardive dyskinesia or deanol may have a beneficial effect on dyskinetic movements that is not inhibited by therapeutic levels of lithium.

Dr. Crews is Assistant Professor of Psychiatry and Dr. Carpenter is Resident in Psychiatry, University of Alabama at Birmingham School of Medicine, Birmingham, Ala. 35294.

IN MEMORIAM

David M. Levy
1892–1977

DAVID M. LEVY, M.D., who died on March 1, 1977, lived and worked during the first 50 years of modern child psychiatry. He offered leadership to the child guidance movement when it was characteristically new, provocative, eclectic, interdisciplinary, invested in therapy, yet mindful of the scientific, the evaluative, and the experimental. He became a model for several generations of child psychiatrists.

He was director of the Institute of Juvenile Research (the first of the modern child guidance clinics), chief of staff of the Institute of Child Guidance in New York, clinical professor of psychiatry at Columbia University, and president of the American Psychoanalytic Clinic for Training and Research. He received many honors, including membership in the Institute for Advanced Study, an honorary lectureship and citation by the Salmon Committee, and, most recently, a citation by the Society for Research and Child Development for his leadership and research in child development for 50 years.

Apart from his leadership in developing treatment programs for children, he was keenly aware of the opportunities for investigation in psychiatric treatment. As an investigator, he achieved fame for his straightforward simplicity, his originality, his range of creativity, and his unyielding honesty. Beginning his career as a neurologist and later trained in psychoanalysis, he exemplified the eclectic point of view. He retained his interest in the biological as well as the psychosocial roots of behavior. He employed a variety of therapeutic modalities. For example, he used psychoanalysis, play therapy (which was painstakingly accommodated to the needs of the individual child), and behavioral modification for the alteration of specific symptoms. His observations were uncomplicated and leaned primarily on the simple, direct authority of what he saw. In so doing, he introduced many new constructs into psychiatry, including maternal overprotection and rejection, affect hunger, sibling rivalry, and oppositional behavior.

Free play was the primary instrument for exploring the child's emotional life. However, play was shaped into situations that yielded to the requirements of scientific procedure, exemplified most brilliantly in his analysis of the hostile act in his sibling rivalry experiment.

His concept of the act as a functional unit in search of a goal was illustrated in his studies of sucking by babies and puppies, in which interference with satiation resulted in unusual oral habits. He showed how to use case records to test hypotheses regarding the origin of childhood behavior disorders, and he reported the impact on chidren of maternal overprotection, rejection, and deprivation. He emphasized the merits of "experiments of nature," and in his classical observations of oppositional behavior, he demonstrated that the normal developmental peak of such behavior occurs between 18 and 24 months.

Similarly, in the study of the baby's memory of inoculation, he established that memory cries did not occur before 6 months of age, so that these memories were not likely to be a source of anxiety for later events.

David was modest in his aspirations, entirely uncontrived and devoid of affectation, objective, straightforward, and free of bias. Always using ordinary language, he was exquisitely austere and clear in his expression. He enjoyed the act of contemplation and he was the most curious of men. His favorite game was the prediction of human events. Disarmingly simple, he was enveloped by a luminous aura of originality, inventiveness, and independence of spirit. He was remarkably self-possessed and his outward composure was, at times, mistaken for absent-mindedness. He was actually intensely aware and impelled by a straightforward interest in the comings and goings of all living things without prejudgment. His fundamental attitude was best described as curious and tender. He understood man's loving nature and accepted his banality, his dissimulation, and, at times, his wickedness. In calmly reporting their interplay, he communicated his overpowering consciousness of the beauty of living things.

WILLIAM GOLDFARB, M.D., PH.D.

LETTERS TO THE EDITOR

This section contains reactions to Journal *articles, statements of opinion, comments on Association activities, requests for information, etc. Letters should be submitted in duplicate to the Editor, who makes all decisions regarding publication. Letters must be typed double spaced throughout and should not contain more than 500 words and 5 pertinent references. Criticisms of published articles will automatically be sent to the author(s) for response. Letters will be edited for clarity and conformance with* Journal *style. We regret that we cannot inform writers of the disposition of letters or return those which are not printed.*

Opiate Receptor – Natural Ligand System: Causal Factor or Defense System?

SIR: Enkephalin administration generates emotional detachment from pain experience, dissociated states of consciousness, and schizophrenia-like motor symptoms such as waxy flexibility and catatonic rigidity (1). On the basis of these observations, a causal relationship (genetic importance) between hyperactivity of the CNS opiate receptor system and severe emotional illnesses has been suggested (2–4). If this relationship does exist, emotional illnesses would be significantly improved by administration of inhibitors of opiate receptor activity. If, however, the organism increases its opiate receptor – natural ligand system to generate an effective defense against the pathogenic agent that is causally related to the emotional illness, such inhibitors would severely impair the patient's condition.

Animal experiments have been performed to obtain conclusive evidence differentiating these two mechanisms (causal factor versus generation of a defense system against it); results were evaluated in view of the available clinical literature. The effects of recurrent pain-related stressful experiences during early postnatal life on the development of the CNS opiate receptor – natural ligand system were studied in the rat (an animal born with 50% of its opiate receptor system, which functions qualitatively on an adult level) (5, 6). Recurrent daily stimulation of the periaqueductal gray matter by means of implanted microelectrodes or daily hot-plate treatment resulted in statistically significant and somewhat permanent increases from 30% to 50% in both CNS opiate receptor activity and natural ligand (enkephalin) content (7). These results suggest that the newborn (and probably the adult) organism is able to mobilize its defenses against pain perception by inhibition of the protopathic system.

The severe withdrawal symptoms observed in infants born to mothers who consume opiates suggest that man is born with a well-functioning opiate receptor system. These symptoms result from the sudden withdrawal of the ligand by cessation of transplacental supply at birth and by generation of the same (or similar) metabolic changes observed in the adult during acute abstinence.

According to current knowledge (8, 9), the future schizophrenic perceives maternal emotions empathetically and experiences hostility, rejection, double-bind communications, etc., in addition to the discomfort generated by the as yet unidentified etiological factors. It seems that such newborns attempt to decrease their discomfort by inhibiting protopathic pain perception through increased activity of their opiate receptor – natural ligand system. This overfunctioning of the opiate system interferes with intracerebral control (1) of the voluntary musculature, a system with an onset during the fourth postnatal month. The resulting tendency toward waxy flexibility and catatonic rigidity reinforces the newborn defense against pain: decreased motility makes it probable that the individual will have fewer new encounters with exogenous sources of pain. Development of this early defense mechanism promotes its future preferential use (9) during exposure to stressful events.

The observations described herein suggest that increased opiate-system functions are developed as attempts to defend against a causally related pathogenic factor; they also caution against attenuation of these defense systems before the causative factors of emotional illnesses are resolved.

On Placebo Effects

SIR: The readers owe thanks to Michael H. Sheard, M.D., and associates for being so explicit regarding their subjects' ability to guess whether they were on lithium ("The Effect of Lithium on Impulsive Aggressive Behavior in Man," December 1976 issue). They reported a "double-blind, placebo-controlled" experiment on the effect of lithium in diminishing chronic aggressiveness. Unfortunately, those subjects whose behavior improved knew they were on lithium (80%,

$p<.01$); moreover, a possibly "surlier" group of subjects who might not have improved so much dropped out of the study as soon as they felt side effects. The authors dismiss this with the assertion that their questionnaire showed these subjects did not feel the drug was improving their behavior, as if conscious awareness were necessary for placebo effect to occur.

What this study does show is that inmates who know they are on lithium and do not drop out because of side effects have fewer "major" and a tendency toward more "minor" aggressive episodes. The explanation for this might as well be placebo effect (known to be enhanced when the placebo is physiologically active like lithium) as any specific action. This would certainly be an interesting and potentially useful finding and might be verified by a replication study with three groups: one on lithium, one on inert placebo, and one on an active placebo that mimicked some of lithium's side effects.

BEN EZRA GREEN, M.D.
Portland, Ore.

Drs. Sheard and Marini Reply

SIR: Dr. Green makes two criticisms of our study: that dropouts from the lithium group might not have improved as much as the subjects we were able to study, and that the lithium subjects' correct medication guesses compromised our conclusions.

With regard to dropouts, since we did not evaluate "surliness," we can neither confirm nor deny Dr. Green's proposal. Not all of the dropouts quit "as soon as they felt . . . side effects": of the 14 lithium subjects who quit, 1 rejoined and completed, 7 quit within 2 weeks of starting medication, and 6 quit after 3–5 weeks. As we pointed out in our report, we found no evidence that subjects who dropped out had different infraction histories than those who completed, and other results (see below) suggest that many dropouts may have been due to an antiaggressive effect.

With regard to the double-blind, we are aware that "conscious awareness" is not a necessary condition for a placebo effect. However, it obviously is a sufficient condition: the behavior of subjects who are aware they are receiving a drug with putative antiaggressive properties may well be influenced by their knowledge. We therefore attempted to evaluate their subjective responses rather than "dismissing" this problem; our evaluation provided no evidence for a frank influence on behavior.

There are three observations that support a specific, rather than a placebo, effect of lithium (1). First, a comparison of placebo subjects who guessed they got placebo with those who guessed lithium reveals no difference in major infractions per man-week while on medication, a slight increase from the premedication to the medication period for those who guessed lithium, and no change for those who guessed placebo. Second, in studies referenced in our report Sheard (2) and Tupin and associates (3) have shown that lithium has an antiaggressive effect in subjects to whom aggression is ego-syntonic: reduced aggressivity causes uncharacteristic anxiety and these men may drop out of the study. Third, the subjects in those studies and in our own had histories of repeated incarceration and a variety of therapeutic and psychopharmacological treatments with no evident improvement in their behavior: they are self-selected to be refractory to amelioration of their violence. For these reasons a placebo effect is a much less satisfactory explanation than a specific antiaggressive effect of lithium.

We discussed the problems of double-blind methodology with lithium at length in a paper (4) referenced in our report and concluded that use of an "active placebo" would be an appropriate strategy to test in lithium psychopharmacology. We have also pointed out that there are several nontrivial conditions which must be met for such a strategy to be valid (4).

Politics or Science?

SIR: "The Why of Fragging," by Thomas C. Bond, M.D. (November 1976 issue), is a disturbing article from a number of standpoints. At the most superficial level it concerns me that the Editorial Board did not show greater discrimination in blocking this unscientific and political document from publication. I cannot fault the author, who obviously represents a defined political position and chooses to support it through the use of "science."

For those readers who may have missed the political position, I would like to raise the following issues not answered by the article.

The author describes a study group, offering no comparative sample and no indication of whether this type of person is usual or unusual among enlistees. Having done psychiatric screening for the military myself, I am aware that he is describing a large number of individuals in the military, not only the ones who "fragged."

A second question is why violence against superior officers experienced a phenomenal increase in one war (the Viet Nam war) compared with all other major wars (World Wars I and II and the Korean war). The author's answer is ostensibly apolitical. He cites the lack of activism, both political and racial, in the persons studied and conjectures that "drugs" led to the difference in this war.

If the same level of analysis were applied to the riots of the 1960s in the inner city, one might have found that individuals who threw Molotov cocktails possessed the same traits or lack of traits as "fraggers." Does that mean we give them individual therapy or blame the difference on "drugs" and the problem is done with? Obviously, we are dealing with larger social issues that catch people up as their victims.

In summary, I find the publication of this kind of article particularly dangerous because it misuses "science" to perpetuate a belief system that blames the victim on the bottom of the social structure. Perhaps I would not feel as disturbed about this article if I could read psychiatric studies of the

military and political leaders who generated and perpetuated a war that killed hundreds of thousands. Surely they warrant more psychiatric inquiry than their relatively ineffective counterparts among the enlistees.

STUART L. OKEN, M.D.
Baltimore, Md.

Dr. Bond Replies

SIR: Dr. Oken finds my article "disturbing"; I find his letter quite annoying and one-sided. His criticisms are largely simplistic, anecdotal, and unsubstantiated, more reflective of predetermined ideas than serious scrutiny of the article itself.

Dr. Oken raises the spectre of political motivations in the article and then elucidates his own political views quite clearly. He appears to want to explain everything on the basis of malevolent social forces, ignoring any interaction of personal forces that might explain why these specific men acted as they did. I would suggest he reread the article, but I doubt he would feel differently.

I would welcome any questions in the spirit of scientific inquiry, but I see no purpose in addressing vague, global criticisms. Deciding who were the offenders and victims in Viet Nam is something to be left to others.

THOMAS C. BOND, M.D.
Belmont, Mass.

Editor's Note. This paper was sent to a highly qualified reviewer who recommended its acceptance and felt that the paper would be of value to psychiatrists in the military and in the Veterans Administration. Dr. Oken faults me for publishing this paper, so in correspondence with him I asked whether he would want me to censor papers. He answered, "The position you occupy as Editor must of necessity warrant your role as censor or filter of information to the APA membership." I disagree; my position is that of a judge of the caliber of manuscripts, and I considered this paper worthy of publication.

Innovation or Fad?

SIR: I am writing about a Clinical and Research Report by David Rosen, M.D., entitled "A Primal Primer for Psychiatrists" (April 1977 issue). Many scientific papers are refused publication every month because the number of sound contributions exceeds your limited space. It is surprising you considered it justified to allot two pages to a testimonial for "primal therapy," recounting a personal experience of the author and an anecdote. The author claimed that he treated 800 patients by this method, but he does not report the results.

The paper proves what every experienced clinician knows—that "almost anything" helps some people. Since the time of Mesmer and long before, we have known of the strong impact of suggestion on susceptible persons, especially if administered in isolation from one's usual environment and supported by a group of believers.

You must be aware that publication in the *Journal* confers an aura of scientific authenticity on the author and his contribution. I hope that the Editor and Editorial Board will show better judgment in distinguishing between unorthodox innovative experimentation and the many fads currently exploiting the public.

ALEXANDER S. ROGAWSKI, M.D.
Los Angeles, Calif.

The Editor Replies

The paper in question was subjected to our usual review procedure and was sent to a person who is highly respected in the field. The reviewer's comments indicated that the paper should be published because it would add to the general level of knowledge about Janov's primal therapy and because there has been little information on the subject in the psychiatric literature. It should also be noted that one of the reasons we developed the Clinical and Research Reports section was to provide a vehicle for publication of papers that presented interesting ideas or observations in a brief form without the more stringent requirements related to methodology, sample size, analysis of data, etc., that apply elsewhere in the *Journal*. This does not mean that we accept mere "testimonials." I feel this paper has something to offer the readership. I regret that Dr. Rogawski does not agree with my judgment, but this is invariably the lot of the Editor.

F.J.B.

Dehumanization in Medical Education

SIR: I heartily applaud the proposals set forth by Paul Jay Fink, M.D., regarding psychiatry's involvement in the training of primary care residents (February 1977 issue). However, I fear that his focus is insufficient.

The main emphasis in the curricula of most medical schools is facts, not feelings. Students learn to repress emotions and to distance themselves from empathic interactions as a way of enduring daily confrontation with illness and death. From the first day, when they are faced with a cadaver, students are given little aid in dealing with their inevitable feelings. Later they learn to minimize the human part of suffering. For example, hospital ward rounds often are conducted with the brusqueness of a department store inventory. A six-week clinical rotation in psychiatry may come too late to begin to counteract these situations. Furthermore, the exposure of an unprepared medical student to the extremes of emotional illness could increase anxiety levels and even lead to a rejection of psychiatry.

The medical school curriculum should include forces to counterbalance this loss of empathy. Students need assistance in dealing with patient distress, anxiety, confusion in a strange environment, and the terror of a malfunctioning body. The medical student can be made aware of the benefits to be gained by enlisting patients as active rather than passive participants in their treatment and recovery.

Psychiatry needs to participate more vigorously in medical education. It is the only "primary care" specialty that must teach its own basic science, and this is frequently postponed until the third-year rotation. Foundations could be laid in the first two years for usable basic concepts and skills: recognition of emotional responses like depression and depressive equivalents, the stages of death and dying, the effects of separation from family on a hospitalized child, patterns of mental functioning and how to examine them, recognition of basic character types and how they might respond to illness, how learning takes place, etc. Clinical time might include

demonstration not only of severe psychiatric illness but also of the subtle variants that are much more common in medical situations. The training during medical school may be the only clinical contact with psychiatry that many students will have for the rest of their lives.

There are many potential benefits from this type of program. We might expect an improvement in patient care and an increase in psychiatric referrals, as well as an enhancement of the relationship between psychiatry and the rest of medicine. We might also find more students desiring to become psychiatrists; there would be more choice in the selection of residents for training programs, leading to an even higher quality of psychiatric practice. Furthermore, a long-term benefit in the form of decreased incidence of malpractice difficulties due to patient-physician misunderstanding and conflict might result.

Physicians have been getting a great deal of bad publicity lately. The traditional image of the kindly doctor has vanished. Some may say that it is not up to psychiatry alone to restore that image, but I believe that we are in the best position to take the initiative.

ELLIOTT M. STEIN, M.D.
Miami Beach, Fla.

Dr. Fink Replies

SIR: Dr. Stein is absolutely correct in his statements regarding the dehumanizing process of medical education and the need for medical school curricula to provide opportunities for dealing with affect-laden material. There has been a nationwide effort to introduce a variety of such learning opportunities into the first two years of medical school so that students' basic science experiences will not rigidify them early in their training. In many schools the development of behavioral science programs has done just what Dr. Stein prescribes with regard to affect, ethics, human development and behavior, and a host of important topic areas. In 1973 the National Board of Medical Examiners introduced a Behavioral Science Examination into the Part I exam. This has required deans and curriculum committees throughout the nation to pay attention to and introduce such topics and courses into the preclinical years. In addition, the nationwide trend to introduce clinical activities in these years also provides an enhancement of this humanizing process in medical education. Unfortunately, many schools have dealt with this issue by either insisting that these experiences be "scientific" or undermining them by disparagement or tokenism.

Over the past two years, a series of articles in the *Journal of Medical Education* has described such courses.[1] Almost every school in the country has introduced some variation on the same theme. Some important ingredients must be included if they are to serve the purposes outlined by Dr. Stein. First, the courses should be organized so that the smallest student-teacher ratio is used. Small-group teaching in groups of 8–10 students to 1 or 2 faculty members is optimum. These groups are improved when there is more than 1 faculty leader so that issues of controversy, uncertainty, and debate can be introduced. At Jefferson Medical College, each group has 3 instructors, a psychiatrist, a behavioral scientist, and a nonpsychiatric physician, preferably from one of the primary care professions. Such groups must be run with the correct combination of structure (for the obsessive-compulsive, content-oriented students) and nonstructure (for the introduction of affect and attitudinal issues). In addition, organized course material dealing with interviewing, communication theory, growth and development, ethics in medicine, legal medicine, and the sociology and economics of medicine, to name a few, should be scheduled as serious, required, and respected parts of the preclinical curriculum.

The goal of a long-term improvement in the doctor-patient relationship for all physicians might be achieved through this and other methods. There is still a great deal of reluctance on the part of medical educators to give psychiatry and behavioral science a proper place in the curriculum, but gradual progress is being made. All of these comments do not negate the position I have taken concerning adequate education of nonpsychiatric physicians at the graduate level as outlined in my article.

PAUL JAY FINK, M.D.

Placement and Evaluation of Southeast Asian Children

SIR: The article by LCDR Richard K. Harding and John G. Looney, M.D., on "Problems of Southeast Asian Children in a Refugee Camp" (April 1977 issue) was interesting as a perspective for our experience working with a family that was caring for a 15-year-old Vietnamese girl whom they were considering adopting. Our contact with this case was through the county mental health center to which the girl was referred by an organization called Foster Care Relocation of Vietnamese Children. The girl had had two brief placements (one with a Vietnamese family) that were not successful because of behavioral problems. She also had had a brief psychiatric hospitalization.

The foster family consisted of the parents, two sons aged 10 and 9, and two daughters aged 4 and 2 (the younger girl is an adopted Korean child). The family brought the Vietnamese girl to the center for evaluation of aggressive behavior, which included calling the police and stating the family was hurting her (when she did not get her way), being mean to their oldest son, and being very demanding. This well-functioning, white middle-class family felt embarrassed and somewhat devastated that their good-will mission was not producing the desired results. The family was aware of the great need expressed by others involved for this placement to be successful.

A lengthy family session plus a number of subsequent conferences with the parents demonstrated clearly that the girl could not tolerate others receiving attention. When asked to share the limelight with her foster siblings, she responded by screaming, being aggressive toward the older son, and/or attempting to elicit intervention from outside persons or agencies.

A psychiatric evaluation performed with the aid of an interpreter showed a pleasant, friendly, well-dressed, illiterate Asian girl with minimal command of English, limited ability to communicate, and short attention span. Her functioning at school, in the family, in the office, and on the "draw a person" test was similar to children we have seen with IQs of approximately 70. On the Vineland Scale she had a socialized age equivalent of 9. The limited information given on the Wechsler Intelligence Scale for Children indicated severe retardation. A Bender Motor Gestalt test confirmed

moderate organicity. The neurological exam and sleep EEG were negative. The girl appeared to be of low intelligence, with previous psychosocial and environmental deprivation. She stated that she had been a servant girl since age 9 and that the woman she worked for in Viet Nam hit her with a stick on the head. The patient was started on 25 mg of thioridazine h.s. The dose was reduced to 10 mg because of morning drowsiness and the patient tolerated this dosage well.

The patient lived with this family for 9 months, but she was not adopted because of the problems described above and has been placed with another family. This case demonstrates the evaluation and placement difficulties that arise when transcultural problems are further complicated by developmental, organic, and emotional disturbances.

BETSY L. ERSLEV, M.S.S., A.C.S.W.
West Chester, Pa.

Confidentiality: A Solution to the Problem?

SIR: I would like to suggest a solution to problems related to confidentiality. Let all physicians provide all patients they see with a complete statement of their account, including diagnosis, method of treatment, and outcome, plus all charges and substantiation thereof. Each patient, then, will have all the information that is needed for legal disclosures, e.g., insurance, employment, school, disability, Social Security, etc. Information-seekers would then go directly to the patient; the patient would decide who will be given this information and who will not. With the patient's permission, physicians might communicate with other physicians for purposes of medical treatment only.

FRANCIS J. BURGIN, M.D.
Syracuse, N.Y.

Methodology in REM Sleep Studies

SIR: I would like to comment on "REM Sleep and Adaptation of Psychiatric Patients: An Application of Sleep Studies" by Ramon Greenberg, M.D., and Chester A. Pearlman, Jr., M.D. (October 1976 issue). The authors' attempt to apply available physiological data (REM latency) to explain psychological phenomena (dream content and patients' current conflicts) seems stimulating and intriguing, but unfortunately the method they used for the study is subject to some criticisms.

The authors used an extremely heterogeneous population. Their criteria for mental illness are vague and ambiguous, and they had no criteria for the selection of the patients (44 male inpatients were selected for study). No baseline information was obtained to enable the authors to compare their data. Physiological variables were correlated with psychological phenomena in a heterogeneous population without any data to justify this. The experimental data are so contaminated that any conclusion drawn from them is open to serious question. For example, shortened REM latency may be due to many factors, such as rebound phenomena following withdrawal from any REM-suppressing agents. It is also not clear whether patients were drug-free during the study.

The authors were blind in the areas that necessitate careful screening (they note that they "never saw the patients or heard anything about their histories") and were not blind in areas where they should have been. Finally, there was no mention of who the therapists were or in what capacity they served. The dynamic orientation of the authors could probably explain the above mentioned flaws in their methodology. If Drs. Greenberg and Pearlman used more stringent criteria for patient selection and dealt with a more homogeneous group, they would certainly be more able to make a reasonable hypothetical bridge between REM sleep characteristics and related dream content and prediction of response to different treatment modalities.

IRADJ MAANY, M.D.
Philadelphia, Pa.

Drs. Greenberg and Pearlman Reply

SIR: It is difficult not to respond by simply asking Dr. Maany to reread our paper. We did not, as Dr. Maany suggests, "attempt to apply available physiologic data (REM latency) to explain psychological phenomena (dream content and patients' current conflicts)." Instead, we used data collected in the sleep laboratory, both physiological and psychological (dreams), to predict the eventual outcome of the patients' treatment programs.

With this in mind, it becomes clear that Dr. Maany's points, methodological criticisms, and suggestions could only make this predictive task more difficult. The fact that we were able to make significant predictions in the face of such problems seems to us to indicate the power and meaningfulness of the sleep laboratory data. Keeping our aim in mind should also make it clear to the reader why we had to be blind to clinical information when we made the predictions. Otherwise, the predictions would have been contaminated by our use of clinical experience. Finally, we specifically mentioned the problem of drugs and drug withdrawal and how such a situation could only work against accurate predictions.

In conclusion, in his attempt to dismiss the implications of the study, Dr. Maany appears to have ignored both the data and the means by which they were collected.

RAMON GREENBERG, M.D.
CHESTER PEARLMAN, M.D.
Boston, Mass.

The Function and Organization of NIMH

SIR: Bertram S. Brown, M.D., clearly summarized the precarious, underfunded state of psychiatric research in his article "The Crisis in Mental Health Research" (February 1977 issue). I disagree with his conclusions that the National Institute of Mental Health (NIMH) should continue as an independent bureau with responsibility for both research and nationwide community mental health center operation. As I understand the largely oral history of the development and eventual separation of NIMH from the National Institutes of Health, this move was given impetus by psychiatrists' views that the future of psychiatry lay not with medicine, but conceptually and politically with a coalition of nonphysician workers in the mental health field. That rationale has been weakened by the failure of social psychiatric research to yield causal information about the major psychiatric syndromes (1) and the expansion of information in psycho-

pharmacology and the neurosciences in the past 20 years. The expansion of the service delivery function has created many problems. The community mental health center development, for all its benefits, has resulted in an illogical balkanization of treatment services in many communities (2). The segregation of psychiatry from the rest of general medical services has been detrimental to patients and psychiatrists, especially in consultation-liaison work and emergency care.

Rather than expanding the role of the psychiatrist, mental health centers have tended to constrict job functions to those of prescription writer and legitimizer of clinical functions performed by other staff members. This narrowing of role has been furthered by the elimination of psychiatrists from most program directorships and a reduction in the percentage of mental health center employees who are psychiatrists.

I believe that these problems dissipate the administrative energies of NIMH personnel and infiltrate the intramural activities of NIMH, bringing about the same conflicts one sees in the field; this seriously hurts the image of the psychiatric profession in the eyes of the public and politicians, as expressed in funding. When total budgetary dollars increase, it is difficult for many politicians to realize that research dollars may be suffering, especially if the service efforts are themselves confusingly referred to as "broad scale experiments," by attaching evaluation components to them. In most cases, the evaluation has been no more than the counting of services and tabulation of data that flow in a one-way fashion to Washington. Outcome research on the cost-effectiveness of psychiatric care in mental health centers remains inadequate.

Suggestive evidence that the more time-intensive group and individual psychotherapies can be provided efficaciously by persons without the expensive training of psychiatrists is leading to redefinitions of what psychiatrists commonly do and what third-party payers will pay them highly to do. The biobehavioral advances of recent years and the stronger role of psychiatry in the education of psychosocially skilled physicians equipped to provide primary care to patients with chronic, multifactorial disorders enable one to make a strong case for psychiatry to work more closely with the rest of medicine. I favor the return of research and training programs to NIH, with limitation of direct service endeavors to pilot projects that are carefully designed and systematically evaluated. Policy decisions for implementation on a larger scale could be made more wisely in this framework, avoiding the costly failures and oversold, unmet expectations that accompanied the "Great Society" programs of the 1960s.

Challenging the Psychiatric Education Establishment

SIR: The publication of "Challenging the Medical Student in a Psychiatry Clerkship" by Leslie S. Linet, M.D. (January 1977 issue) leads me to write this letter to set forth a challenge to the psychiatric education establishment. Isn't it about time that experimental training programs attempted to collect some valid information to substantiate the rhetoric used?

Some measures of success for evaluating training programs are feasible and should be used. The first step would be to specify the changes in knowledge, skills, or attitudes expected as a result of a new program. For example, the author might have considered reporting National Board scores in psychiatry for this group of students. Faculty not involved in this particular clerkship might have reviewed and judged the adequacy of the students' written case reports; it would be even more convincing if evaluation included faculty ratings of videotaped interviews by the students compared with others in different clerkships. These methods could assess the degree to which the students in this clerkship develop skills and knowledge in treating acute psychiatric illness.

To assess selection bias, it would be useful to have information on how students are selected or select themselves. In a more complete evaluation of such a clerkship, it would also be interesting to have follow-up at six months to a year to see how much was retained and to follow the students on other clerkships to see to what extent the skills and knowledge are used on other services and what relevance the clerkship had for their other clinical work. One could also see if the clerkship changed students' attitudes toward psychiatry in general, toward their own interest in entering psychiatry as a specialty, or toward referring future patients to psychiatrists.

Although there has been precious little evaluation of training programs, there may be some rays of hope. Eaton and associates have published criteria for evaluating psychiatric education programs (1). In addition, after 40 years of evaluating the results of training programs by certifying psychiatrists, the American Board of Psychiatry and Neurology has authorized the development of a design for a validation study to determine the relationship between performance on the examination and clinical competence in the field (2).

With increasing pressure for public accountability, psychiatric training programs must demonstrate what effects they are having on students and trainees in order to maintain credibility. I hope that psychiatric educators will step up their interest in this area.

Dr. Linet Replies

SIR: Dr. Liptzin is right in suggesting several measures for evaluating teaching techniques. However, there should be a place in a noted publication such as the *Journal* for reports on methods, whether they are education or therapy techniques, without the requirement of a research design. I entirely agree that the pressure for accountability in psychiatry must be addressed, but it is not necessary that every psychiatrist do research to validate a particular hypothesis or to validate psychiatry in general. We have among our ranks psychiatrists who are qualified and have chosen to do this kind of research. Dr. Liptzin is Acting Chief of the Program

Analysis and Evaluation Branch of NIMH and is, I trust, qualified to lead us in this direction.

Treating Blurred Vision Associated with Antipsychotic Medication

SIR: While working with patients whose psychiatric condition necessitates maintenance on long-term antipsychotic medication, we have noted that blurred vision is a frequent untoward side effect. This can be particularly incapacitating to patients whose normal functioning requires extensive use of near vision and can lead to problems with drug compliance.

Hyperopia occurs in patients on antipsychotics because of the anticholingeric properties of these agents; this iatrogenic hyperopia causes the blurring of vision. Although this is a well-recognized phenomenon, it is usually either ignored by the treating psychiatrist or accepted as an unfortunate but untreatable side effect. A review of the literature revealed that no significant work has been done in this area.

We have found that the topical use of pilocarpine hydrochloride solution temporarily reverses the hyperopia and allows a more normal visual functioning. Pilocarpine has proved to be a relatively safe drug, suitable for long-term use in patients with glaucoma without the high risk of cataract development that is associated with certain anticholinesterase agents.

In a trial with 12 consenting patients who had blurred vision as a consequence of antipsychotic medication, treatment with pilocarpine hydrochloride, 2% solution, produced improvement in vision in all cases. Our initial treatment regimen was one drop applied to each eye three times a day. It should be kept in mind that individual dosage requirements vary, and titration of dosage is necessary. In these patients we have not observed the development of any significant untoward effects associated with the cholinomimetic actions of the alkaloid. In 3 patients, however, initial administration of the topical solution resulted in myopia. Adjustment of the medication dosage resulted in improved vision in these patients, and the initial myopia resolved with a decrease in dosage.

We are presently planning a carefully designed study to substantiate these observations.

Correction

There was an error in "Criteria for the Diagnosis of Alcoholism," by the Criteria Committee, National Council on Alcoholism (129:127–135, August 1972). The first entry in the right-hand column of table 2 (p. 130) should read: "Serum osmolality (reflects blood alcohol levels): every 22.4 increase over *290* mOsm/liter reflects 50 mg./100 ml. alcohol."

BOOK REVIEWS

On Psychosis, *by Paul Schilder; edited by Lauretta Bender. New York, N.Y., International Universities Press, 1976, 576 pp., $22.50.*

This collection is a tribute to the vision of Dr. Schilder. Although the papers are based on his experience from 1930 through 1940 with psychotic patients, they are replete with cogent observations that resonate with the interests of contemporary psychiatrists. Dr. Schilder's holistic approach to the psychoses is indicated by the subjects of his papers, which range from anatomy to psychoanalysis.

The lead article, which has not been previously published, summarizes most of the pertinent issues. Dr. Schilder viewed the psychoses as a regressive response to an overwhelming situation. He suggests that although the cognitive difficulty in psychosis is different from that in organic disorders, the disturbances are sufficiently similar to postulate an organic defect in psychosis. The regression that occurs in psychosis affects not only the libido but also the functions of the ego.

Dr. Schilder accepts the idea that narcissistic regression occurs in the psychoses, but he points out the confusion that has resulted from the failure to differentiate between narcissism as a developmental phase and narcissism as a libidinal investment of the self. He disagrees with those who posit an objectless psychic state in the infant, citing evidence that from the first the infant responds to stimuli from the outer world. However, the infant barely distinguishes what occurs inside his/her body from that which happens outside. Psychic development depends on the differentiation of inside from outside. Projection, introjection, and identification play an important role in this differentiation and in the development of psychic structure. Interference with development results in ego and superego deficits that render an individual vulnerable to psychosis. Psychosis is a response not only to the anxiety and guilt engendered by a conflictual situation but also to the helplessness and perplexity associated with the inability to cope with a situation.

Many of the subjects to which the author alludes in his comprehensive first paper are elaborated in subsequent papers. Dr. Schilder repeatedly tries to delineate the nature of the organic basis of the psychoses. The exact nature eludes him, but on the basis of careful clinical observation and psychological testing he indicates that the disturbances in the perceptual and motor faculties of the psychotic patient are not the same as those in which anatomical or toxic lesions can be demonstrated. In purely organic syndromes there is little connection between the patient's history and the illness, but in the psychoses symptoms are related to past experiences and have symbolic meaning. The perceptual disorders, including absence of pain in catatonia and psychotic distortions of body image as well as the thought disorder characterized by lack of differentiation of signal from referent, although suggestive of organic pathology, can be attributed to no known organic disorder.

Because Dr. Schilder did not believe in a sharp distinction between the somatic and the psychic but thought that psychological disorders may be associated with somatic changes and vice versa, he stressed the importance of the psychotherapeutic approach to the psychoses. In these papers he discusses the psychodynamic issues in both schizophrenia and manic-depressive phychosis that may have etiological significance as well as those which are important in therapy. He hopefully anticipated the day when we would be better informed about somatic factors.

Dr. Schilder recounts his experiences with insulin coma, pentylenetetrazol (Metrazol), and nitrogen inhalation, which were the somatic therapies in his time. Although these treatments have not proved useful and Dr. Schilder was sometimes too enthusiastic about them, his conviction that the psychoses are psychosomatic illnesses has been substantiated by continued investigation.

Adolf Hitler: A Family Perspective, *by Helm Stierlin. New York, N.Y., Psychohistory Press (Atcom), 1976, 153 pp., $9.95.*

This book is a gallant and ambitious attempt to explore the mystery of Adolf Hitler by considering him, like any other child, the product of the family that reared him. Helm Stierlin uses as his major conceptual tool his own well-articulated theory of transactional modes that operate as the covert organizing background to the more overt, specific child-parent interactions. In the case of Hitler Dr. Stierlin focuses chiefly on the delegating mode, in which the child's ties to his/her parents impel the child to fulfill certain missions, sometimes acknowledged but often quite out of awareness. This delegated role can be healthy but is often derailed, leading to various pathological consequences, which Stierlin describes in detail.

In brief summary, Stierlin's theory is that Hitler was bound (another transactional mode) and delegated by his anxious, pathetic mother, who, brutalized and exploited by her husband, Hitler's father, poured into Adolf all of her frustrated yearnings, which were augmented by the early deaths of her first three children. The missions that Hitler was to fulfill were to both redeem and avenge her. His mother's desperate grip, however, was stifling and elicited in Hitler a profound ambivalence that was turned against the projected figures who became for Adolf the enemies of Germany when the country itself assumed the role of his mother after her death.

Hitler's mythic enemies, of course, were the Jews, but how they came to occupy this position seems to me the weakest part of Stierlin's formulation. He relies on acceptance of the seminal role in the development of Hitler's anti-Semitism attributed by Rudolph Binion to the Jewish doctor Eduard Bloch, who cared for Hitler's mother during her final

illness. This, in turn, depends on the assumption of a massive unconscious reaction formation because the small amount of evidence available indicates that Hitler was consciously friendly in his feelings and actions toward Bloch.

Stierlin's portrait of Hitler does not depend on family theory alone, although this is central to it. There are also contributions from psychoanalysis and group theory, from current and past history, and from the sociology of the German character. The book is marked by a broad erudition that makes it consistently interesting to read.

What can be said about the success of Stierlin's attempt to make Adolf Hitler explicable in psychohistorical terms? It is clear that the author, like other Hitler theorists, is hampered by the lack of reliable and detailed information about Hitler's early life and family relationships. This paucity of facts unfortunately opens the way to unsupported speculation that, to some extent, cannot be avoided, although Stierlin attempts to stick to what is known. The picture of Hitler that emerges, as the product of a close-binding mother and a distant, rejecting father, has become a psychiatric cliché, a family constellation that has been used to explain the development of a bewilderingly wide variety of pathological character structures and clinical conditions.

It is clear that Hitler's family background and experiences were not at all unusual for German and Austrian children of his generation. It is difficult to conceive of this rather banal breeding ground as the prime factor responsible for the gestation of a monster like der Fuehrer. One is left with the feeling that although much of what Stierlin says about Hitler seems plausible, it constitutes a thin and unsatisfactory explanation of his boundless malignity. We are left with the Iago problem, and to this psychology can make only modest contributions.

PAUL CHODOFF, M.D.
Washington, D.C.

Depression: Clinical, Biological and Psychological Perspectives, *edited by Gene Usdin, M.D. New York, N.Y., Brunner/Mazel, 1977, 338 pp., $15.00.*

This is the eighth publication in the American College of Psychiatrists' series of annual surveys. It reviews the more prominent of the many perplexing features of depressive states. Almost 60% of the text—7 of the 13 chapters—is devoted to an exposition of the biological substrate of depression. The authors of these chapters detail the salient evidence concerning the role of genetics, psychoneuroendocrinological features, biochemical research findings, somatic treatment methods, toxicological manifestations of psychotropic medications, and certain aspects of the phenomenology of sleep and sleep disturbance as they relate to the depressive states.

Although the psychogenic aspects of depression are not neglected in this book, Dr. Usdin frankly provides the rationale that led to the preferential focus on biological aspects in his introduction: "There is . . . a voluminous body of psychoanalytic and psychotherapeutic literature regarding depression, while the field of pharmacotherapy is a relatively new one in which dramatic strides . . . are being made."

Each of the 13 chapters is appended by a series of reference citations that amplify for the interested reader the necessarily compacted texts of the individual essays. The nature of the material treated does not lend itself to easy reading. In effect, the compleat clinical psychiatrist these days has to become a polyglot. He/she has to be conversant with the languages of neurobiological sciences in order to translate their research into the idiom of patients. The gap between the enzymology of neurotransmitters and psychodynamics has not yet been bridged by even a unifying conceptual grammar. This deficiency, among other things, leads to an unavoidable difference in the styles of the individual essays in their attempts to encompass a comprehensive perspective of the clinical, biological, and psychological aspects of the depressive states. Nevertheless, this compilation of studies achieves the objective of the American College of Psychiatrists in that it provides a vade mecum for an eclectic approach to a better understanding of depression.

HOWARD P. ROME, M.D.
Rochester, Minn.

Harry Stack Sullivan: His Life and His Work, *by A.H. Chapman, M.D. New York, N.Y., G.P. Putnam's Sons, 1976, 270 pp., $8.95.*

Patrick Mullahy, the foremost interpreter of Sullivanian views, lamented that no clinical psychiatrist—preferably a former student of Sullivan—had brought forth a comprehensive exposition of Sullivan's ideas. Thereupon, Mullahy proceeded to publish *Psychoanalysis and Interpersonal Psychiatry* (1), a monumental book presenting Sullivan's views. *Harry Stack Sullivan* by Arthur H. Chapman adds some interesting biographical details about Sullivan to Mullahy's scant six pages.

Although it is not so comprehensive a book as Mullahy's, Chapman's book makes for quicker, easier, and more interesting reading. Easy readability is sometimes thought to be a vulgar attribute, but the fact that the writing itself is interesting, taken together with the intrinsic interest of Sullivan and his works, makes for a book that will not only attract and inform psychiatrists, most of whom are probably already Sullivanian enough, but also inform and interest the general reader. Chapman is a psychiatrist with a knack for writing lucidly and entertainingly.

The book begins with a chapter on "The Life and Emotional Problems of Harry Stack Sullivan," in which Sullivan's loneliness, homosexual preferences, private life, and tendencies to mystify his own childhood and adolescence are brought out of the closet. Following the biographical material, which is discreet and respectfully incomplete, Chapman brings Sullivan's principal views out into the open in chapters concerned with Sullivan's basic concepts of interpersonal relationships; participant observation, cognitive distortions, consensus, anxiety, and dynamisms; child and adolescent development; psychotherapy; and Sullivan's relevance to such current problems as racial discrimination and intergenerational difficulties.

Chapman steps carefully in and around some of the stark inconsistency, murkiness, and unsound formulations to be found in the writings and lectures of Harry Stack Sullivan. Chapman is not idolatrous, but he is definitely favorable to Sullivan's more consistent, more sensible, better reasoned, clearer, and sounder conceptualizations. All in all, this is a book that will edify the professional as well as the patient, the mildly curious as well as the devoted follower of Sullivan, and many of the friends and supporters of psychotherapy of all persuasions. One hopes that Sullivan and books about Sullivan are not blacklisted by analytic institutes because this study by Chapman could aid many trainees in

analysis and psychiatry to gain a useful working knowledge of the unhappy genius Harry Stack Sullivan. Like Freud, Sullivan was exceedingly close to his mother; Sullivan did not have a happy life, but he did not believe in Thanatos. Chapman's book is a most welcome contribution.

From Shaman to Psychotherapist: A History of the Treatment of Mental Illness, *by Walter Bromberg, M.D. Chicago, Ill., Henry Regnery Co., 1975, 350 pp., $4.95 (paper).*

Walter Bromberg has been writing about the history of psychiatry for 40 years, which makes him one of a very select and durable group of workers who have continued their researches for an extended period of time. I believe that Dr. Bromberg has not received the credit and recognition he deserves for his historical contributions. His *The Mind of Man* (1), which appeared in 1937, is a nicely written book covering the total sweep of past events in psychiatry and is still very useful, especially for laypeople and young psychiatrists who wish to understand how modern psychiatry has evolved. Bromberg's second book, written with John K. Winkler (2), used a biographical style to study the field. *Man Above Humanity* (3), published in 1954, is a more explicit study of the history of psychotherapy, a theme running through all of Bromberg's historical writings.

Man Above Humanity is my favorite of Bromberg's works. Less concerned with historical and social background, he concentrated in this book on the details of therapy—its philosophies and its methods. By so doing, he made a rich research contribution to our understanding of how psychotherapy has changed over the years.

From Shaman to Psychotherapist is a completely rewritten work, although it appears in a softbound format and is described by the author as the fourth edition of *The Mind of Man*. The revisions are impressive. Dr. Bromberg has retained the chronological approach of *The Mind of Man*, which naturally dictates a similarity of total structure, but the development of the story and the illustrations used are new. Among the topics discussed are early therapy, showing the role of the shaman and the extensive use of magic; the growth of rationalism during Greek and Roman times; the tensions that developed between Christianity and the emerging naturalism of the Renaissance, manifested in the witchcraft epidemics; and the impact of the increased use of the scientific method in the seventeenth and eighteenth centuries, which led to the "coming of age" of the asylum.

The last half of the book is devoted to more modern subjects: the derivation of hypnotism from mesmerism, conflicts in the hospital setting, the growth of faith healing and psychotherapy, the emergence of psychoanalysis, the recent burgeoning of group and encounter therapies, and, finally, organic treatments in psychiatry.

Bromberg's book is notable in that it is based on a wide reading of original literature and many years of contemplating the issues involved. It may be safely recommended to residents and others interested in learning about psychiatry and its origins. It is well written and has many useful references, although more extensive coverage of the growing secondary literature of the past 25 years (e.g., on the concept of the Victorian woman and her symptoms as exemplified in hysteria) would have made this textbook of greater value. The book ends with a serviceable index. Dr. Bromberg has every reason to be proud of this completely revised fourth edition of *The Mind of Man*.

ERIC T. CARLSON, M.D.
New York, N.Y.

Genetic Engineering: Threat or Promise? *by Laurence E. Karp, M.D. Chicago, Ill., Nelson-Hall, 1976, 230 pp., $15.00.*

This is a book about the role of genetics in the diagnosis and therapy of disease; it is also a book about reproductive engineering. The first part includes such current topics in genetics as counseling, eugenics, genetic screening, genetic therapy, and prenatal diagnosis of genetic disease. Except for artificial insemination, the subjects discussed in the second part of the book are for the distant or not-so-distant future: sex determination, ectogenesis (fertilization and maturation of embryos in vitro), parthenogenesis (development of ova to maturity without fertilization), cloning, and the synthesis of life from nonliving matter.

Although the book is written for the layperson, all of the topics have psychological implications with which every psychiatrist should be familiar. In genetic counseling, for example, the emotional significance of the information given is considerable; Karp discusses the role of the counselor in helping the family make decisions, the issue of invasion of privacy, and the assessment of the intellectual and emotional status of the counselee. He also refers to the psychological difficulties in genetic screening caused by the knowledge that one has a genetic disease and to the psychodynamic implications of artificial donor insemination. Typical of the many believe-it-or-not facts in this informative book is Karp's estimate that between 5,000 and 10,000 babies are born in the United States each year through artificial donor insemination.

As the title of this book implies, the author is concerned mainly with the biological and ethical consequences of the new genetics. As a professional and as a citizen the psychiatrist cannot avoid involvement in the larger practical and moral issues posed by genetic knowledge. This is a good book with which to start learning.

The author sides with the more optimistic contingent in the field of genetics, reiterating that time, informed consent, and democratic institutions will prevent misuse and pointing out with clarity and imagination the potential benefits of genetic engineering. The polemical tone of his sallies at those who are more pessimistic often seems to express more sarcasm than scientific dispassion. However, regardless of his point of view, Karp is well equipped as a prominent obstetrician and geneticist to present the many facts on medical ge-

netics and human reproduction with which no psychiatrist can remain unfamiliar. The bibliography is up-to-date, and the index and glossary make the book useful for reference.

JOHN D. RAINER, M.D.
New York, N.Y.

Stress Response Syndromes, *by Mardi Jon Horowitz, M.D. New York, N.Y., Jason Aronson, 1976, 362 pp., $15.00.*

This volume is a scholarly investigation of stress response syndromes. Dr. Horowitz brilliantly provides a natural history and clinical depiction of a psychopathological state as it is manifest in the context of various personality styles. He also presents results of psychotherapy research that are applicable in the clinical setting. Probably the most unique accomplishment of this volume is the author's success in treating his subject comprehensively and organizing it in such a way that the reader is likely to experience a sense of rational order. *Stress Response Syndromes* should have a broad general appeal to psychiatrists because it addresses syndromes that are often disguised but are always in evidence among some of our patients.

Dr. Horowitz details his strategy and preliminary tactics early in the book. First he describes the psychopathological or maladaptive states under consideration. Then he considers the patient in the context of his/her current phase of response to stress and the patient's disposition in terms of personality for organizing and processing of defenses, thoughts, emotions, and coping patterns during such states. Finally, Dr. Horowitz examines therapeutic relationships and techniques currently in use in terms of how or why they may or may not be useful. He reviews psychoanalytic and contemporary psychological models and makes an extensive effort toward their integration. He briefly considers psychobiological models but does not analyze them.

Three basic styles of countering painful and intrusive emotional responses to stress are given major consideration in separate chapters of the book. These are titled "Inhibiting Operations: Reactions to Stress and Psychotherapy with Hysterical Personalities," "Switching Maneuvers: Reaction to Stress and Psychotherapy with Obsessional Personalities," and "Sliding Meanings: Reaction to Stress and Psychotherapy with Narcissistic Personalities." These exemplary models provide a vivid insight into the significance of personality trait variation in the manifestations of stress response as well as in the effects of various psychotherapeutic modalities. Specifically, Dr. Horowitz provides a knowledge of which therapeutic interventions may be effective and why or why not. In a series of discussions he uses clinical examples that consider how single external stress events trigger divergent reactions. Included are chapters on the loss of a limb, visual shock, automobile accidents, death of a parent, suicide of a friend, and multiple stress events.

Dr. Horowitz' efforts in this volume provide a well-organized and flexible conceptual model for understanding the stress syndromes, permitting improved clinical management and future systematic assembly and critique of clinical knowledge. We are indebted to Dr. Horowitz because he has rendered a rational scientific description and study of a psychopathological state in such a way that we may sequentially conceptualize, challenge, and improve on it.

WILLIAM E. THORNTON, M.D.
Chicago, Ill.

The Behavioral Management of Anxiety, Depression and Pain, *edited by Park O. Davidson, Ph.D. New York, N.Y., Brunner/Mazel, 1976, 188 pp., $13.50.*

One great value of behavior therapy has been its focus on observables and its subsequent refusal to consider phenomena not subject to objective verification. Thus the title of this book presents a contradiction of terms. Is it valid to apply behavioral methods to affects and sensations—subjective states that do not seem to be reliably verifiable by an observer?

The authors are aware of this issue. For example, Davidson states that there is

> increasing evidence that all three of these conditions can be conceptualized as operant responses or, at least, that large components of the anxiety, depression, or pain experience consist of operant responses, and that these are subject to modification using behavioral technology. (p. xi)

Meichenbaum and Turk state,

> Something is happening to behavior therapy! Its "learning theory" basis is being challenged and is being replaced, in part, by a cognitive orientation. . . . Illustrative of this shift in emphasis is our treatment program . . . of modifying the client's internal dialogues [i.e., self-statements and images]. . . . A more appropriate title than behavior therapy would be cognitive-behavior therapy. (pp. 1–2)

Keeping in mind the question of the validity of employing behavior therapy for nonobservable events, I was reassured by other aspects of the authors' approaches. Both in the definition and initial evaluation of the patient's clinical state and in the evaluation of the effectiveness of treatment methods they rely heavily on objective measures. Laboratory simulations of relevant stressors, home visits for naturalistic assessment, and tape-recordings of patient-spouse interactions are some of these procedures.

The five chapters of the book are derived from papers presented at a conference. Fordyce's chapter on behavioral management of chronic pain and illness gives a lucid, convincing discussion of the relationship between two types of pain behavior: respondent pain behavior involves the patient's response to pathophysiological processes, including the sensation of pain; operant pain behavior involves the patient's communication of his/her distress to others. It is toward the latter that behavioral management is primarily, but not exclusively, directed. Fordyce also describes the medical treatment system in which such a patient finds himself/herself, effectively delineating the forces at work on the two main characters in this social system—patient and physician. These analyses lead Fordyce to the rational treatment plan detailed in the chapter.

The other four chapters include a discussion of stress-inoculation training for anxiety, anger, and pain by Meichenbaum and Turk and a discussion of preventive behavioral approaches to individuals at risk for maladaptive responses by Poser, who emphasizes the lack of demonstrable effects of preventive interventions. There are two chapters on the behavioral treatment of depression, one by McLean and one by Lewinshon and associates; these discuss several behavioral models of depression, emphasizing cognitive and behavioral approaches to the problem areas delineated.

In summary, this volume focuses on important clinical areas for psychiatry, employing a largely cognitive emphasis with behavioral methodology for evaluation. It will be especially interesting to psychology graduate students, psychiatric residents, researchers in these areas, and the industrious practicing psychiatrist—who probably can find some of these areas presented more readably elsewhere. The format of the book is heavily textual, with few figures. The price is laudably low.

THEODORE WEISS, M.D.
Philadelphia, Pa.

Culture-Bound Syndromes, Ethnopsychiatry, and Alternate Therapies: Vol. IV of Mental Health Research in Asia and the Pacific, *edited by William P. Lebra. Honolulu, Hawaii, University Press of Hawaii, 1976, 299 pp., $16.00.*

This book, based on one of the East-West Center conferences, offers an excellent selection of papers that bring a great deal of order to the phenomena of mental health research in Southeast Asia and the Pacific. Anyone visiting this part of the world cannot help but be impressed by the lack of modern psychotherapeutic programs and the abundance of indigenous health methods on which the majority of people rely. The persistence of the population explosion and the rising costs of modernization suggest that modern programs will probably not be developed in the foreseeable future and that the indigenous programs will continue to provide care for the mentally ill. These techniques provide many of the universal elements of therapeutics as well as many culture-specific features geared to special problems in specific cultural settings.

The conference organizers sought to comprehend some of the therapeutic factors inherent in indigenous programs. Their goal was to find ways of collaborating with the native folk healers, who are certainly in closer contact with the population than the medical communities.

In Taiwan, where adequate facilities exist, many patients choose the more familiar and more intimate folk methods. The Japanese, who rank high in industrialization, literacy, and life expectancy, pursue both modern and indigenous therapies simultaneously. The majority of patients attending Yaji Sasaki's clinic in Tokyo also sought assistance in the increasingly popular new religions or in magicoreligious cults, which proved especially effective for neurotic patients. One of the more sophisticated techniques is Morita therapy, which is used in the treatment of *shinkeshitu*, a culture-bound obsessional-phobic state. Morita therapy combines a week's rest period with behavior modification techniques involving meditation and performing routine chores.

Many Asian participants in the conference reported difficulty in applying Western psychotherapeutic approaches in their own cultures. The emphasis on familial obligations and ancestral ties among the Japanese, as exemplified in the guided meditation of Naikan therapy, could not be reconciled with the emphasis on self-reliance and individualism found in the analytically oriented therapies. This raises important questions about the culture-specific nature of our own psychiatric approaches, which may be more value laden and less universally applicable than we thought. Recognizing this, we may be able to understand the current enthusiasm for a variety of quasi-therapeutic cults in the United States; these might be more responsive to the current needs of troubled people than conventional therapeutic methods.

The book covers a range of important substantive and methodological themes in transcultural psychiatry. A series of articles examines *Latah*, epidemic hysteria, possession, and *malgri*, a previously unreported culture-bound syndrome found in the Mornington Islands in New South Wales. This condition, characterized by fatigue, pain, and vomiting, develops after failure to eliminate traces of land food before entering the sea. Other chapters focus on indigenous healing practices in the Philippines, Polynesia, Malaysia, Taiwan, Korea, Japan, China, and among the Maori of New Zealand. This volume will be a useful addition to the growing field of transcultural psychiatry.

ARI KIEV, M.D.
New York, N.Y.

Death, Dying, and the Biological Revolution: Our Last Quest for Responsibility, *by Robert M. Veatch. New Haven, Conn., Yale University Press, 1976, 318 pp., $12.95.*

Society is failing to meet its obligation to its dying members. Too frequently people with terminal illnesses suffer isolation and neglect in hospitals, receive overzealous treatment by physicians, and are kept in ignorance of their situation by families and medical personnel. This state of affairs, as reported by observers of the medical care system and by dying patients themselves, has generated widespread concern.

According to Robert Veatch, the problem is one of rights. He believes that people facing death are being stripped of human freedom and responsible choice. Dying patients, he claims, have a moral right to know the truth about their condition, no matter how painful, and a legal right to refuse treatment, regardless of the reason. By means of closely reasoned and persuasive arguments Dr. Veatch arrives at a series of policy positions that he feels would ensure these rights and restore human dignity. He urges public debate on the issue, and this clearly written volume should provide a stimulus.

Dr. Veatch writes in a refreshing style and takes a clear stand on a host of philosophical, social, medical, ethical, and legal issues. He brings new and practical thinking to bear on such matters as the definition of death and the donation of organs for transplantation, subjects of continuing discussion and controversy.

Approaching his subject from a number of perspectives, he enriches his treatment of it. However, his changes in perspective may confuse the unwary reader at times. For example, the right to refuse treatment, which the author emphasizes, is a legal but not necessarily a moral right. Consequently, a patient may have a legal but not necessarily an ethical right to refuse treatment whenever he/she wants to and a physician may have a legal but not necessarily a moral obligation to discontinue treatment whenever a patient asks him/her to. The ethical positions of physician and patient are not satisfactorily defined.

For the physician, Dr. Veatch's book makes painful reading. He blames the medical profession, which he calls a "technocratic elite," for depriving dying people of their rights. He views physicians as motivated by self-interest and a desire for power and perceives them as using deceitful and high-handed tactics to maintain their authority. Thus he joins a growing attack on the professionalism of physicians so evident in the courts and the public press. His call for a physician-patient relationship with dying patients characterized

by mutual cooperation rather than the more traditional parent-child mode of interaction is sensible, but his attack on the medical profession is, for the most part, uncritical and one-sided.

However, this is an important book. It promises to become a force for needed change and deserves the attention of those who are concerned about the welfare of dying patients, their families, and their communities.

RUSSELL NOYES, M.D.

Crusaders Criminals Crazies: Terror and Terrorism in Our Time, *by Frederick J. Hacker, M.D. New York, N.Y., W.W. Norton & Co., 1976, 346 pp., $9.95.*

Terrorism is a social phenomenon that is of interest to clinical psychiatrists. In this somewhat popularized volume, Dr. Hacker applies his personal experience with terrorists and his theoretical constructs to the attempt to understand phenomenological differences between various kinds of terrorists—those who are psychotic, those who have criminal and mercenary intent, and those who represent a social cause. Each type uses a different method of negotiating with the public and the media, each handles victims in a different manner, and each requires a different response on the part of officials.

Dr. Hacker makes a number of statements regarding the appropriate role of the media. In a postscript on the Israeli rescue at Entebbe he laments the fact that it received such favorable publicity; he suggests that the event should be viewed somberly by authorities in spite of its successful outcome. Generally, Dr. Hacker stresses the seriousness of terrorists and the causes they represent, reflecting on the fact that these causes are often valid. He counsels patience and describes the role of verbal dialogue with terrorists.

Some parts of this book are rhetorical; one section presents an engrossing account of the author's involvement in the Hearst case and his experiences with hijackers in Vienna in 1973. Dr. Hacker is a professional who has struggled to understand a widespread and alarming behavior; as such he enlightens us with regard to episodes we are often called to comment on as psychiatrists.

JOHN R. LION, M.D.
Baltimore, Md.

A Complete Guide to Therapy: From Psychoanalysis to Behavior Modification, *by Joel Kovel, M.D. New York, N.Y., Pantheon Books, 1976, 273 pp., $10.00.*

Today, people seeking relief from crippling neurotic symptoms, freedom from limiting neurotic character traits, or improvement of their lives through discovering and freeing latent resources within themselves are confronted with a variety of therapies. Dr. Kovel discusses the principles and techniques of these therapies so that each person can make what he/she perceives to be the most appropriate choice.

Following a general discussion of his concepts of adult neurosis and treatment, Dr. Kovel describes 14 types of therapies, beginning with Freudian psychoanalysis and its derivatives and a variety of individual and group approaches classified under the human potential movement. In this latter group are included such divergent approaches as Rogerian therapy, est, various group therapies, and behavior therapies. Following a summary of the concepts, goals, and techniques characterizing each therapy, Dr. Kovel ends each chapter with a synopsis in which he anticipates the reader's questions regarding indications and contraindications of each therapy in comparison with the others.

Dr. Kovel points out that all neurotic conflict is part of the totality of the individual's unique life experience. He believes that a common denominator lies in our advanced capitalistic social organization, which he feels imposes contradictions on all aspects of personal life. He acknowledges, however, that his belief that a free socialistic state would reduce or eliminate neurotic conflicts is an "experiment which has to wait its turn." Once a neurotic state develops, it takes on a life of its own, basic aspects of which are repressed.

Dr. Kovel considers Freudian psychoanalytic theory to be "indispensable for an authentically human psychology poised dialectically between biology and society." He says that psychoanalysis helps to conceptualize the irrational in rational terms and points out that most of the current therapeutic schools owe their impetus to Freud.

In spite of substantial differences, all therapies offer some model of neurotic disturbance and call on the patient to relive his/her conflicts in terms of their model. Beyond this similarity there is a great deal of dispute and confusion, with each therapy claiming superiority over all others.

Dr. Kovel sees the human potential movement as a distinctly contemporary American trend arising out of our affluent but emotionally unsatisfactory culture. Belief in the perfectibility of man provides some people with a "scientifically based" faith in a godless world. Dr. Kovel wisely cautions that one should bring the quality of emotional stability with himself/herself when joining human potential groups rather than enter them in search of it.

This book both satisfies and disappoints. As a guide for a troubled person seeking the best route to health it fails because of the inherent nature of neuroses, with their repressions, defenses, distortions, and rationalizations. Unfortunately, the perplexed cannot be their own diagnosticians. The effort to fairly present the pros and cons of each therapeutic approach while only subtly indicating disagreements among them is not likely to make the choice easier. However, to an interested layman the book is quite valuable for the information it presents in a clear, eloquent, and literary fashion. It is delightful reading for those who wish to learn about foreign lands, but, unhappily, it is not a guide for the traveler himself/herself.

LEWIS L. ROBBINS, M.D.
Glen Oaks, N.Y.

Prescriptive Psychotherapies, *by Arnold P. Goldstein and Norman Stein. New York, N.Y., Pergamon Press, 1976, 334 pp., $16.50; $10.00 (paper).*

In formulating the goals and purposes of this book, the authors propose that psychotherapy be much more specific. *Prescriptive Psychotherapy* addresses itself to the interaction of patient, therapist, and treatment and deals with "which type of patient meeting with which type of therapist for which type of treatment will yield which outcomes." Conversely, the authors state that a nonprescriptive point of view holds that the therapist's preferred treatment approach is equally and widely applicable to most patients.

With this purpose in mind, the authors have collected 11 papers written by various workers in the area of psychotherapy. These papers have been published in various journals and are included because the authors of the book view them as contributions to prescription development. At this point we come to one of a number of curious contradictions in the book. There is a section on prescription building that describes various steps at least preconsciously familiar to many of us. Certainly the imagery of a prescription is to most of us a medical one. The contradiction posited is that the authors themselves and a number of the other contributors criticize what they term the medical model, meaning in this context a developmental point of view, a focus on the significance of antecedent events and relationships, diagnosis, and a plan of treatment based on this comprehensive view of the patient. Although the authors favor prescriptive psychotherapy they oppose what they call the medical model because diagnosis means labeling and/or because knowing something of how the patient came to his/her current difficulty in some way interferes either with the set of the therapist or the course of the treatment.

Schlesinger's paper is a notable exception to this point of view. He points out that labeling is not diagnosis and that he does not share the view that diagnosis is an unnecessary precursor to treatment. Schlesinger also makes some effective comments about the categorizations of expressive and supportive psychotherapy. His discussion of supportive psychotherapy is worthy of attention in that he considers it more specific than commonly perceived. He suggests that we consider in what sense a patient needs support and that both expressive and supportive psychotherapy have their place and time in the treatment of any given patient.

Throughout the book considerable emphasis is placed on rather specific patient-therapist matching. One paper seemed to suggest that these matches might be developed to such an extent that there would be therapists who would treat only obsessional, hysterical, or schizophrenic patients. I find this hard to imagine from a practical point of view and troubling from the point of view of education and training. The psychiatric residency training programs with which I am familiar anticipate that residents will acquire the capacity to diagnose and treat a wide array of patients.

The final section of the book proposes a series of specific treatment modalities for a list of disorders, including psychoneuroses, sexual deviations, smoking, bronchial asthma, obesity, and schizophrenia. The recommendations are based on reviews by the authors of treatment results reported in the literature for each condition. The prescriptions, their expected effectiveness, and the methods by which the authors arrive at their recommendations can best be characterized as naïve.

JACOB SWARTZ, M.D.
Boston, Mass.

Participant Observation, *by Leston Havens, M.D. New York, N.Y., Jason Aronson, 1976, 174 pp., $10.00.*

This book promises to develop "a systematic psychotherapeutic technique that can be called, in Sullivan's words, participant observation." The author also compares participant observation with existential and psychoanalytic therapeutic strategies. As he develops this idea he differentially links the various clinical situations in which participant observation may best be used. Throughout the book Dr. Havens asserts that psychotherapy is a rational process in which the therapist makes conscious decisions about which techniques should be used to achieve specific goals. He includes clinical examples from his own practice, from his students' case reports, and from Sullivan's writings.

An active, interpersonally focused therapy that emphasizes the real aspects of the patient's history is the core of participant observation. Counterprojection, a technique that is typical of this approach, assumes that the patient projects onto the therapist distortions from the patient's past. The goal of the counterprojective technique is to remove the patient's projections by thwarting their development (transference) and deflecting them onto a "screen" that the therapist and patient can look at together. This serves to isolate the behavior of important real people of the past and allows objective review, thwarting the development of any intense feelings or fantasies about the therapist while promoting an increasingly accurate appraisal of the past. Subsequent intervention continues along the same lines, using a process Dr. Havens identifies as widening and balancing. Each successive clarification brings the patient and therapist closer to the real past.

Dr. Havens points out that psychoanalytic and interpersonal theory are equally concerned with the past; however, the interpersonal approach focuses on reality while psychoanalysis focuses on fantasy. Dr. Havens also states that objective-descriptive psychiatry seeks symptoms and signs while psychoanalysis seeks fantasies, existentialism seeks feelings, and interpersonal psychiatry seeks "the facts."

Through clinical examples Dr. Havens brings the reader a rich fund of information that begins to approach a point of deliberate use of specific techniques for specific situations. He focuses particularly on the usefulness of Sullivanian interpersonal psychiatry for borderline and paranoid patients (chapters 6 and 7 are especially useful in this regard).

I liked the general thrust of this book—the interpersonal/reality focus, the matching of techniques to situations, and the clarification of process. However, the book suffers badly from a lack of organization and clarity. As an example, counterprojective interpretation, a central focus of the book, is never carefully defined. Furthermore, there are sections in which the author starts to delineate major concepts and never seems to quite achieve that end. The breezy style only adds to this sense of imprecision. The book reads more like the free exchange of a seminar than an orderly, systematic, and scholarly exposition of theoretical and clinical material, which the field so badly needs. The book is full of great promise but falls short of its mark. Perhaps even worse, it may reinforce the myth that psychotherapy is unintelligible, unteachable, and incapable of being described accurately and precisely.

If read as a compilation of extensive case notes, *Participant Observation* is a rewarding and useful book for the senior clinician or advanced student. However, should the reader expect more, disappointment seems likely.

JOE PAUL TUPIN, M.D.
Davis, Calif.

Studies in Violence and Television, *by Melvin S. Heller, M.S., M.D., and Samuel Polsky, J.D., Ph.D. New York, N.Y., American Broadcasting Co., 1976, 503 pp., no price listed (spiral bound).*

Ten studies conducted over a five-year period are presented in this book. Five of the studies were conducted with two groups of institutionalized children who were hypothesized to be both vulnerable to television stimuli and predisposed to violent behavior. One of the groups consisted of emotionally disturbed children with secondary learning disabilities; the second group contained children from broken homes who had minimal or no emotional or learning disabilities. Beyond age range, sex, and race, few specifics are given about these children, although six clinical histories of emotionally disturbed children are given at the end of the book as typical examples.

Using clinical observations and a variety of psychological tests, the authors studied the influence on the children of violent television shows, violent cartoons, and action-adventure dramas with socially useful ("pro-social") themes. In general, the authors found no significant increase or decrease in aggressive or violent behavior in the children after they had seen any of these types of programs.

Another study reported in this volume hypothesized a relationship between cognitive styles (Kagan's reflection-impulsivity) and cognitive controls (Santostefano's leveling-sharpening) and the response of four groups of children to a television show with violent and prosocial content. A questionnaire regarding the children's viewing habits was also given to the children's parents. Few correlations were noted in the first part of this study; however, the answers to the questionnaires showed that children with special education needs or learning disabilities spent more time watching television and less time in other activities than children in regular school classes.

Three of the remaining studies were surveys. Two involved poor, black, young adult violent offenders, and the other involved white, middle-class, young adult college students. Among other data, the information gleaned dealt with drug use, violent behavior, and television viewing habits. About 25% of both groups reported that television was unrealistic and useless for learning anything. At least 20% of the offenders indicated that they had learned various criminal techniques from television programs.

The final study looked at the effects on violent offenders of television programs with various levels of violent content. The authors concluded that the only significant finding was that the more violent shows produced more recall of violent material.

Although these studies are interesting, I found this book rather difficult to read. The information it reports tends to be incomplete, typographical errors are numerous, and the data in the tables are occasionally inconsistent with the conclusions drawn or with data noted in the narrative. The results of the studies of children would imply a negation of the hypothesis that these children were predisposed to violence rather than of the hypothesis that violent television shows lead to violence. This point is especially important in light of the fact that none of the violent offenders came from environments like those of the study children, i.e., residential treatment and, apparently, a Catholic boys' home.

Despite these and other methodological difficulties and the typographical errors already noted, I feel that this book is a useful addition to the literature on television and violent behavior. It is likely to be most useful to the interested researcher (it has more than 100 pages of details on the tests and questionnaires used in the studies) than to a general reader seeking up-to-date reviews.

Dual Problem:
marked agitation
with depression
...a common problem in psychiatric practice.
MSD
MERCK
SHARP&
DOHME
For a brief summary of prescribing
information, please see last page of this advertisement.

Dual-action TRIAVIL®

containing perphenazine and amitriptyline HCl

Marked agitation accompanying depression is a common problem in psychiatric practice, a problem often requiring dual-action therapy to effectively cope with both components of the disorder. TRIAVIL 4-25 helps treat both. A formulation particularly suited to psychiatric practice when higher doses are required, TRIAVIL 4-25 affords the psychiatrist the opportunity to treat marked agitation—each tablet containing 4 mg of the tranquilizer, perphenazine—while helping to relieve the coexisting depression with 25 mg of the tricyclic antidepressant, amitriptyline HCl.

helps treat both the marked agitation and the depression

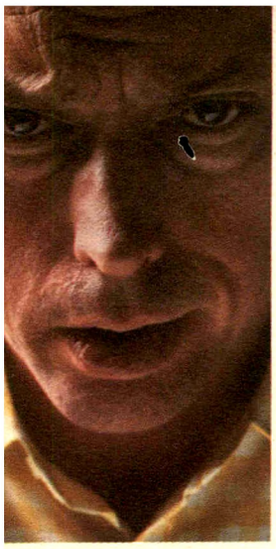
An antidepressant alone may be adequate when the accompanying anxiety is mild, but dual-action TRIAVIL should prove more appropriate when the anxiety or agitation (accompanying depression) is moderate or severe.

The four formulations of TRIAVIL permit the psychiatrist to treat a relatively broad spectrum of depressed patients who manifest symptoms ranging from moderate anxiety to severe agitation, and allow for individualized dosage adjustment.

The advantages of dual-action TRIAVIL in psychiatric practice.

With TRIAVIL, as anxiety or agitation with depression is relieved, the patient may become more accessible and cooperative. Many symptoms such as insomnia, fatigue, anorexia, and functional G.I. complaints are frequently alleviated; symptomatic relief may enable the patient to function more effectively in his daily activities, and the psychotherapeutic process itself may be aided.

TRIAVIL simplifies therapy; encourages compliance.



A single tablet encourages patients to take medication properly and reduces the risk of dosage confusion and error. Cost of therapy to the patient is usually less than when the components are prescribed individually. To date, clinical evaluations of TRIAVIL have revealed no undesirable reactions peculiar to the combination.

Treatment with TRIAVIL– a balanced view.

TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. It is not recommended in children or during pregnancy. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to other drugs or mask other disorders. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information, please see following page.

for moderate to severe anxiety or agitation and depression

DUAL-ACTION Triavil®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

INITIAL THERAPY FOR MANY PATIENTS
TRIAVIL® 2-25 (or TRIAVIL® 4-25) t.i.d. or q.i.d.

FOR FLEXIBILITY IN ADJUSTING MAINTENANCE THERAPY
TRIAVIL® 2-10 (or TRIAVIL® 4-10)

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.

Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric crisis hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) have been reported and can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but some times persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw. Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. Fine vermicular movements of the tongue may be an early sign of the syndrome. The full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

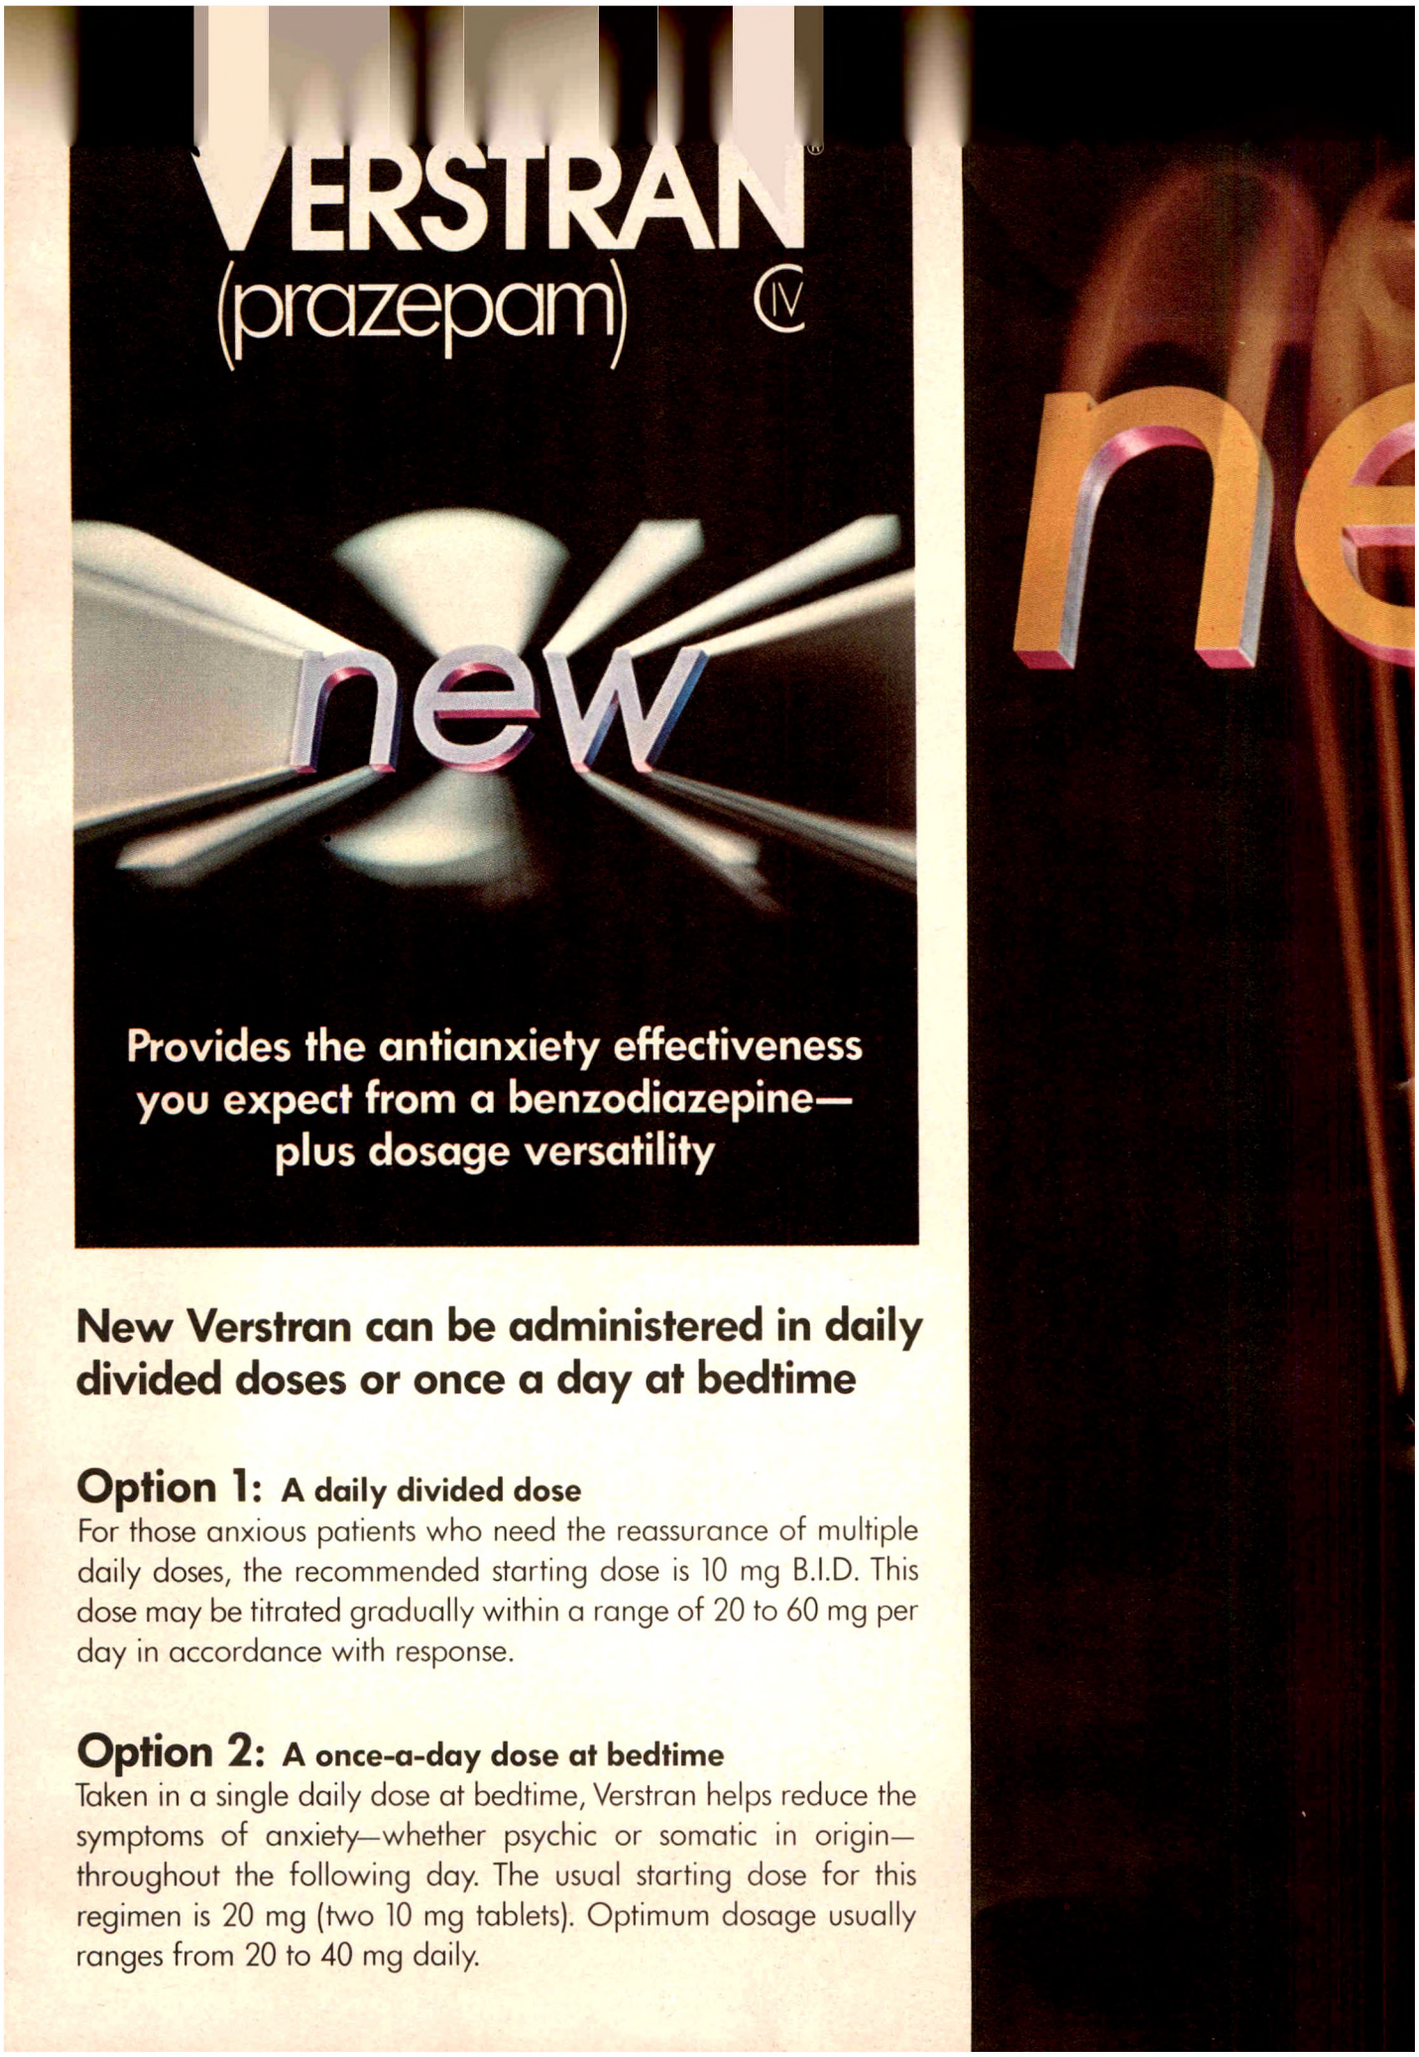
Other side effects are skin disorders (photosensitivity, itching, erythema urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; other adverse reactions reported with various phenothiazine compounds, but not with perphenazine, include grand mal convulsions, cerebral edema, polyphagia, pigmentary retinopathy, photophobia, skin pigmentation, and failure of ejaculation.

The phenothiazine compounds have produced blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after long term administration of some phenothiazines. Although it has not been reported in patients receiving TRIAVIL, the possibility that it might occur should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia have also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs and must be considered when amitriptyline is administered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; increased intraocular pressure; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.



OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

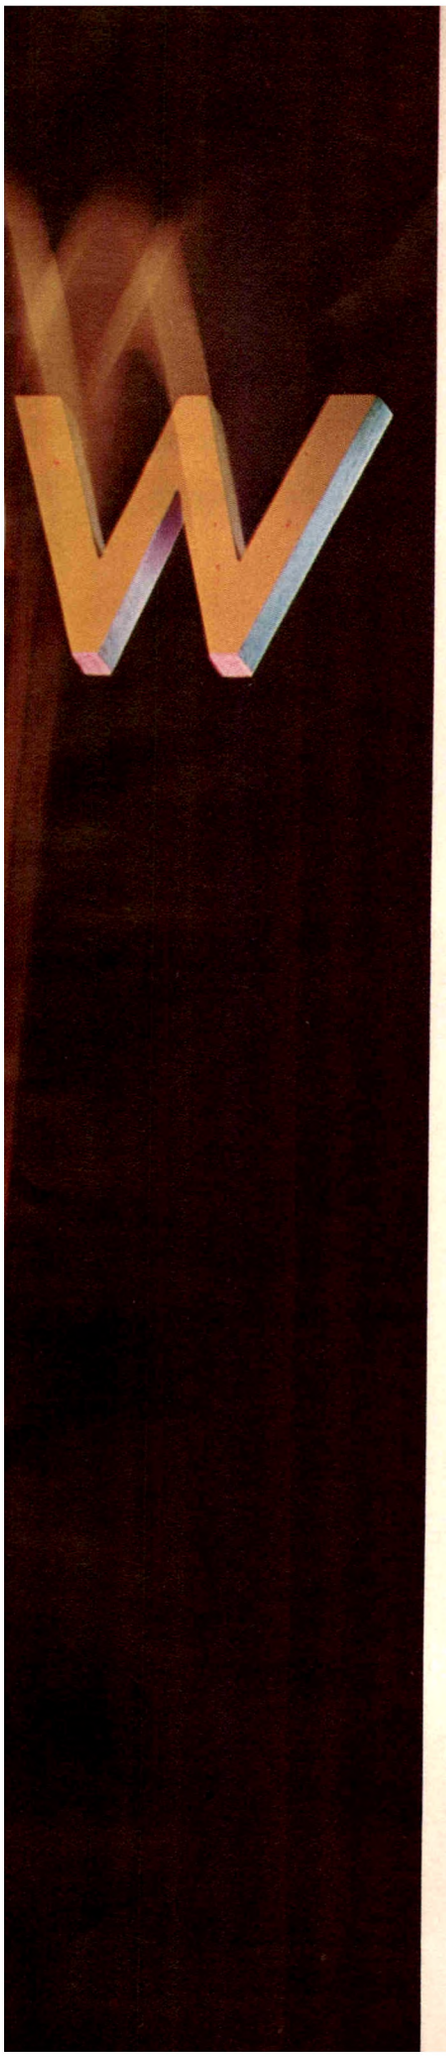
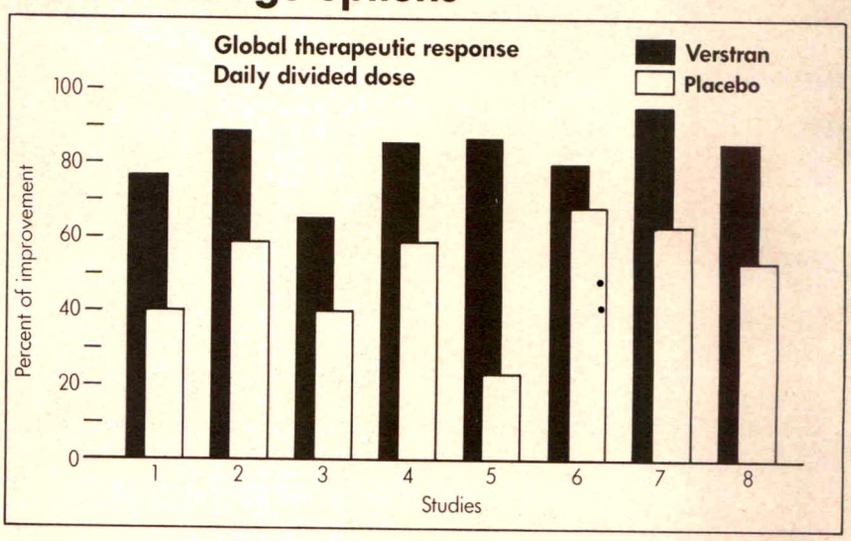
MERCK SHARP & DOHME

Warner/Chilcott Introduces
new
VERSTRAN®
(prazepam) CIV
A new addition for the treatment
of anxiety



New Verstran can be administered in daily divided doses or once a day at bedtime

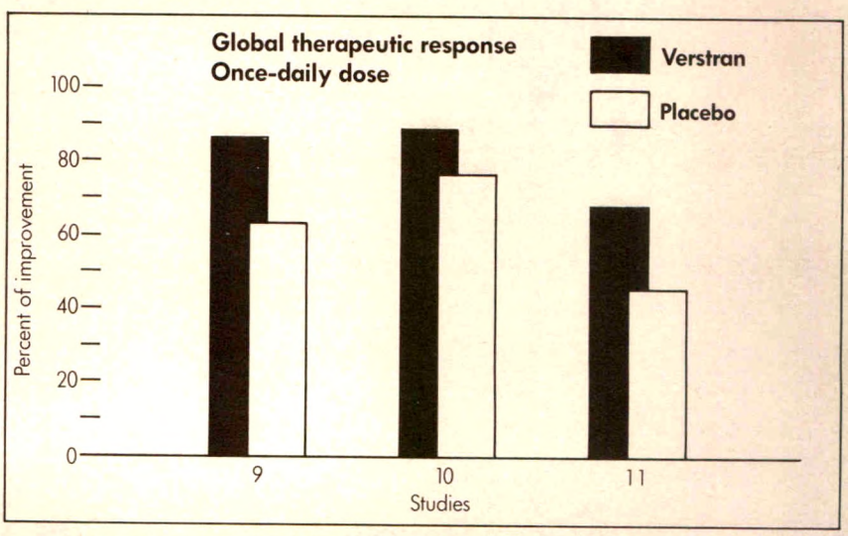
Option 1: A daily divided dose



For those anxious patients who need the reassurance of multiple daily doses, the recommended starting dose is 10 mg B.I.D. This dose may be titrated gradually within a range of 20 to 60 mg per day in accordance with response.

Option 2: A once-a-day dose at bedtime

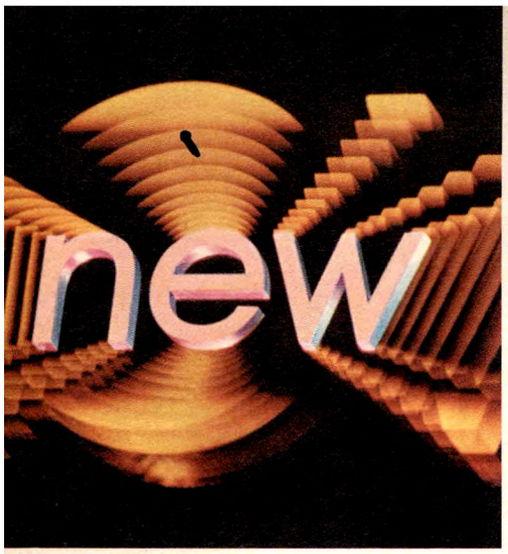
Taken in a single daily dose at bedtime, Verstran helps reduce the symptoms of anxiety—whether psychic or somatic in origin—throughout the following day. The usual starting dose for this regimen is 20 mg (two 10 mg tablets). Optimum dosage usually ranges from 20 to 40 mg daily.



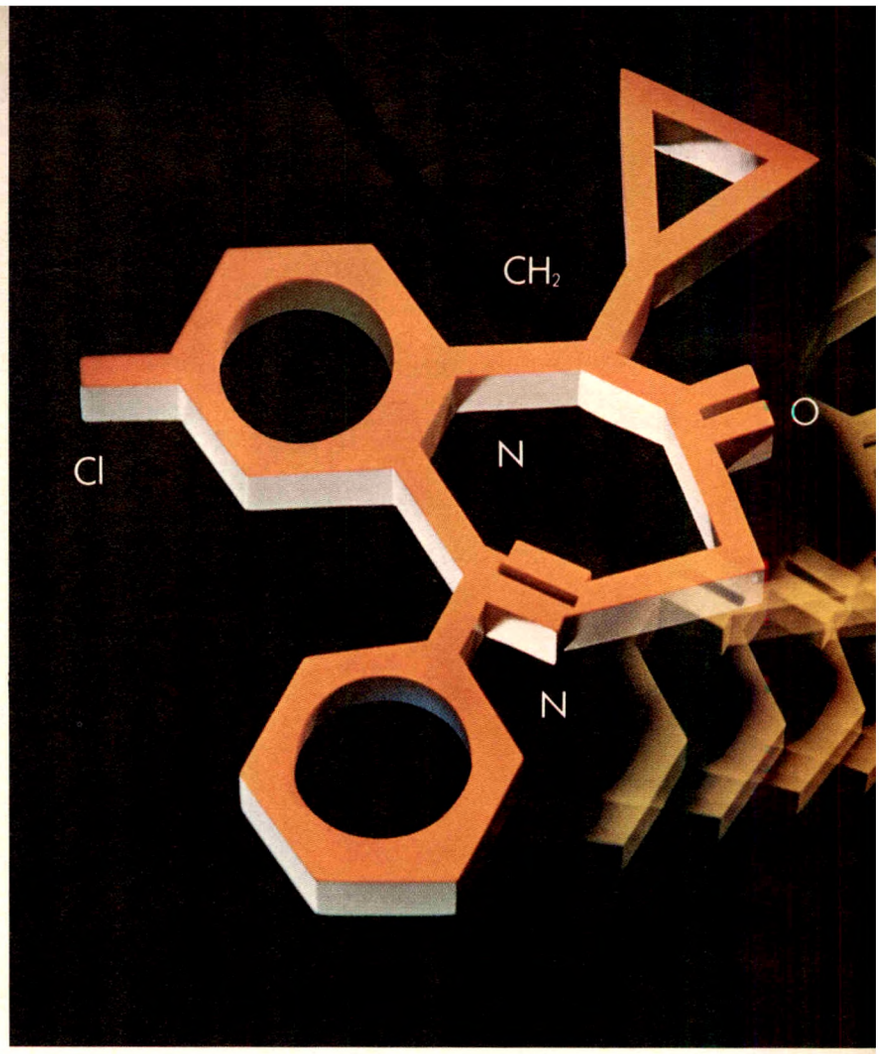
Eleven double-blind studies totaling 560 patients confirm the clinical efficacy of both dosage options*†

Four hundred and four patients suffering nonpsychotic clinical anxiety were given Verstran (228 patients) or placebo (176 patients) in a daily divided dose according to a randomized, double-blind design. Dosage of Verstran was within the recommended limits.

Target symptoms rated include: anxiety, depressive mood, irritability/hostility, tension and insomnia. Global Improvement Ratings were made at week 2, 3, or 4.



One hundred and fifty-six patients suffering nonpsychotic clinical anxiety were given Verstran (70 patients) or placebo (86 patients) once daily at bedtime according to a randomized, double-blind design. Dosage of Verstran was within the recommended limits.



Target symptoms rated include: anxiety, depressive mood, irritability/hostility, tension and insomnia. Global Improvement Ratings were made at week 3 or 4.

*Data on file, Warner/Chilcott Medical Department.

†The number of patients cited represents those evaluated at final observation.

Please see last page of this advertisement for full product information.

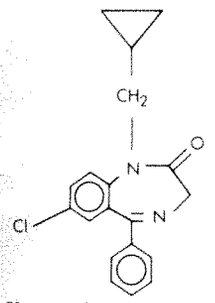
New Verstran provides the simplicity of a single 10 mg tablet strength

Verstran is available in one 10 mg tablet strength only. Titration is simplified, and dosage is easy for the patient to remember. Scored tablets facilitate precise titration.

■ **New Verstran.**
Effective for the symptomatic relief of a wide range of anxiety conditions — whether psychic or somatic in origin.

■ **New Verstran.**
The option of fully effective divided daily or single nighttime dose.

■ **New Verstran.**
The simplicity of a single tablet strength.



■ **New Verstran.**
Side effects are characteristic of benzodiazepine drugs.*

*Please see last page of this advertisement for warnings, precautions and adverse reactions.

Verstran® (prazepam) ℞

Caution: Federal law prohibits dispensing without prescription.

Description: Verstran (prazepam), a benzodiazepine derivative, is identified chemically as 7-chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2H-1,4-benzodiazepin-2-one. The molecular weight is 324.8 and the structural formula is as follows:

Clinical Pharmacology: Studies in normal subjects have shown that Verstran (prazepam) has depressant effects on the central nervous system. Oral administration of single doses as high as 60 mg and divided doses up to 100 mg t.i.d. (300 mg total daily dose) were without toxic effects.

Single oral doses of Verstran in normal subjects produced peak blood levels at 6 hours postadministration, with significant amounts still present after 48 hours. Verstran was slowly absorbed over a prolonged period, rather constant blood levels were maintained, and excretion was prolonged. The mean half-life of prazepam measured in subjects given 10 mg t.i.d. for one week was 63 (± 15 s.d.) hours before and 70 (± 10 s.d.) hours after multiple dosing—a nonsignificant difference. Human metabolism studies showed that prior to elimination from the body, prazepam is metabolized in large part to 3-hydroxyprazepam and oxazepam.

Indications: Verstran (prazepam) is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

Contraindications: Verstran (prazepam) is contraindicated in patients with a known sensitivity to the drug and in those with acute narrow angle glaucoma.

Warnings: Verstran (prazepam) is not recommended in psychotic states and in those psychiatric disorders in which anxiety is not a prominent feature.

Patients taking Verstran should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery, including motor vehicles.

Because Verstran has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, including phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants. The effects of alcohol may also be increased.

Physical and Psychological Dependence: Withdrawal symptoms similar in character to those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepine drugs. These symptoms include convulsions, tremor, abdominal and muscle cramps, vomiting and sweating. Addiction-prone individuals, such as drug addicts and alcoholics, should be under careful surveillance when receiving benzodiazepines because of the predisposition of such patients to habituation and dependence.

Precautions:

Use in Pregnancy and Lactation:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Verstran (prazepam) a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug. In view of their molecular size, Verstran and its metabolites are probably excreted in human milk. Therefore, this drug should not be given to nursing mothers.

In those patients in whom a degree of depression accompanies the anxiety, suicidal tendencies may be present, and protective measures may be required. The least amount of drug that is feasible should be available to the patient at any one time.

Patients taking Verstran for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed. Hepatomegaly and cholestasis were observed in chronic toxicity studies in rats and dogs.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

Pediatric Use: Safety and effectiveness in patients below the age of 18 have not been established.

Adverse Reactions: The side effects most frequently reported during double-blind placebo-controlled trials employing a typical 30 mg divided total daily dose and the percent incidence in the Verstran (prazepam) group were: fatigue (11.6%), dizziness (8.7%), weakness (7.7%), drowsiness (6.8%), lightheadedness (6.8%), and ataxia (5.0%). Less frequently reported were: headache, confusion, tremor, vivid dreams, slurred speech, palpitation, stimulation, dry mouth, diaphoresis, and various gastrointestinal complaints. Other side effects included: pruritus, transient skin rashes, swelling of feet, joint pains, various genitourinary complaints, blurred vision, and syncope. Single nightly dose, controlled trials of variable dosages showed a dose-related incidence of these same side effects. Transient and reversible aberrations of liver function tests have been reported, as have been slight decreases in blood pressure and increases in body weight.

These findings are characteristic of benzodiazepine drugs.

Overdosage: As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

If vomiting has not occurred spontaneously, it should be induced. Immediate gastric lavage is also recommended. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though unlikely, may be controlled with Levophed® (levarterenol bitartrate) or Aramine® (metaraminol bitartrate). Caffeine and Sodium Benzoate Injection, USP, may be used to counteract central nervous system depressant effects.

Dosage and Administration: Verstran (prazepam) is administered orally in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 20 to 60 mg daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a divided daily dose of 10 mg to 15 mg. (See Precautions.)

Prazepam may also be administered as a single dose daily at bedtime. The recommended starting nightly dose is 20 mg. The response of the patient to several days' treatment will permit the physician to adjust the dose upward or, occasionally, downward to maximize antianxiety effect with a minimum of daytime drowsiness. The optimum dosage will usually range from 20 to 40 mg.

Drug Interactions: If Verstran (prazepam) is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monamine oxidase inhibitors or other antidepressants.

If Verstran is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

How Supplied: Verstran (prazepam) 10 mg light blue, scored tablets in bottles of 100 (N 0047-0276-51).

STORE BETWEEN 59°-86° F (15°-30° C).

VERSTRAN®
(prazepam) ℞

A new addition for the treatment of anxiety – whether psychic or somatic in origin

When depression is worse in the morning...

consider the antidepressant with the a.m./h.s. option

Early morning can be the depressed patient's "darkest hour"—the time when he most feels the need for help. Taken at the low point of the classic depressive diurnal rhythm, Norpramin (desipramine hydrochloride) in the a.m. may help patients get started with daily responsibilities, and encourage participation in various forms of psychotherapy.

The a.m. option
Clinical studies show that a single daily administration of Norpramin is as effective and well tolerated as the same quantity given as a divided dosage. This means that Norpramin may be given once daily, morning or bedtime, whichever is most appropriate to the patient's therapeutic need, drug response and activity patterns. A.M. dosage of Norpramin can be especially useful when your depressed patient feels more depressed in the early morning. Morning administration may also help reduce the potential for confusion when other agents are prescribed concomitantly at bedtime.

The h.s. option
For those patients who experience a sedative response to Norpramin, a bedtime dose is most appropriate. Evening administration of Norpramin rarely produces morning hangover.

Minimal daytime drowsiness —permits an active schedule
With Norpramin, problems of daytime drowsiness and morning hangover are largely avoided. Minimal daytime drowsiness can be especially important for patients who must perform daytime activities at home or at work.

Early therapeutic response— builds hope and provides encouragement
While full therapeutic effect may require two to three weeks, onset of action has often been observed in two to five days. Although results have been variable, the weight of scientific reports suggests a faster onset of action with desipramine than with either imipramine or amitriptyline.

Norpramin®
(desipramine hydrochloride tablets NF)

25 mg., 50 mg., 75 mg., 100 mg., 150 mg.

for the patient who must function during the day

Merrell

See following page for prescribing information.

Norpramin®
(desipramine hydrochloride tablets NF)

Brief Summary

Indications: Norpramin (desipramine hydrochloride tablets NF) is indicated for the relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Desipramine hydrochloride should not be given within two weeks of treatment with a monoamine oxidase inhibitor. Contraindications include the acute recovery period following myocardial infarction and hypersensitivity to the drug. Cross sensitivity with other dibenzazepines is a possibility.

Warnings: 1. Extreme caution should be used in patients: (a) with cardiovascular disease. (b) with a history of urinary retention or glaucoma. (c) with thyroid disease or those on thyroid medication. (d) with a history of seizure disorder. 2. This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. 3. *Use in Pregnancy:* Safe use during pregnancy and lactation has not been established. 4. *Use in Children:* Norpramin is not recommended for use in children. 5. This drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. Therefore, the patient should be cautioned accordingly. 6. In patients who may use alcohol excessively, it should be borne in mind that the potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions: This drug should be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with drugs of this class. If possible, dispense in child-resistant containers. It should be kept out of reach of children. Reduce dosage, or alter treatment, if serious adverse effects occur. Norpramin therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates and may cause exacerbation of psychosis in schizophrenic patients. Use cautiously with anticholinergic or sympathomimetic drugs. Response to alcoholic beverages may be exaggerated. In the concurrent administration of ECT and antidepressant drugs one should consider the possibility of increased risk relative to benefits. The sedative effects of Norpramin and benzodiazepines (e.g., chlordiazepoxide or diazepam) are additive. Both the sedative and anticholinergic effects of the major tranquilizers are additive to those of Norpramin. Discontinue as soon as possible prior to elective surgery because of possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients on desipramine hydrochloride. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is neutropenia.

Adverse Reactions: *Cardiovascular:* hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke. *Psychiatric:* confusional states (especially in the elderly), hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis. *Neurological:* numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus. *Anticholinergic:* dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, hypotonic bladder. *Allergic:* skin rash, petechiae, urticaria, itching, photosensitization, edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs. *Hematologic:* bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue. *Endocrine:* gynecomastia, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels. *Other:* jaundice (simulating obstructive), altered liver function; weight gain or loss, perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia. *Withdrawal symptoms:* Though not indicative of addiction, abrupt cessation after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: *Usual adult dose:* 100 mg. to 200 mg. per day. Dosages above 200 mg. per day are not recommended. *Initial therapy:* Should be administered at a low level and increased according to tolerance and response. It may be administered in divided doses or a single daily dose. *Maintenance:* Lower adequate dose once daily to maintain remission. *Adolescent and geriatric patient dose:* 25 mg. to 100 mg. per day, in single or divided doses. Dosages above 100 mg. are not recommended.

Coverage and Utilization of Care for Mental Conditions Under Health Insurance —Various Studies, 1973–74

By Louis S. Reed, Ph.D.
Consultant in Health Economics, American Psychiatric Association

This book reports six studies that add to the growing body of data demonstrating the feasibility of covering mental illness under health insurance. Although in some ways it may be considered a supplement to APA's 1972 book **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (Reed, Myers, and Scheidemandel), all of the data are new. The studies cover the following areas:

- Utilization of mental benefits under the Blue Cross and Blue Shield plan for federal employees, documenting that a "plateau" in the use of these benefits was reached in 1973–74.
- Comparison of benefits for mental and other illnesses under selected employee health benefit plans.
- Coverage of mental illness under collective bargaining agreements of selected unions.
- Utilization of care for mental conditions under the Canadian health insurance program, which gives the same coverage for mental as for other conditions.
- Updating of information on Blue Cross benefits for hospital care of mental illness.
- Data from selected Blue Cross and Blue Shield plans on coverage and utilization of mental conditions, with emphasis on major medical coverage.

S M T W T F S
YOU KNOW
HOW LONG
IT WORKS!

HERE'S HOW WELL IT WORKS

Rapidly effective in acute schizophrenia[1]

Average length of hospitalization was 6.1 days (range 4 to 8) for 13 acutely psychotic schizophrenic patients treated with Prolixin Decanoate using the rapid neuroleptization technique. Dosage the first 72 hours averaged 73.2 mg.

Psychotic symptoms diminished rapidly during the first week and continued to abate throughout the 2-month study.

Statistically significant improvement in 13 target symptoms of the Brief Psychiatric Rating Scale, including disorientation, hostility and uncooperativeness, occurred between pretreatment and final evaluation.

Often works where others fail...[2]

Of 52 chronic schizophrenic patients, hospitalized an average 17.5 years, 71% showed clinical improvement after Prolixin Decanoate therapy (25 mg every 7 to 14 days). 32 patients were refractory to prior therapy, including haloperidol combined with chlorpromazine or thioridazine.

General mobilization of the patients was the most significant effect. 7 patients could be discharged from the hospital. In 30 patients refractory to other medication, Prolixin Decanoate tended to inhibit withdrawal symptoms.

...at a fraction of the cost

Prolixin Decanoate therapy at a maintenance dose of 25 mg. every 28 days can cost from 53% to 69% less than the lowest maintenance dosages of several oral medications (see table below).

Comparison of estimated annual hospital costs for oral and injectable therapy, given the following examples:

Drug	Assumed adult dosage*	Form and potency	Cost per unit	Annual cost
Prolixin Decanoate®	12.5-100 mg every 28 days	5 ml vials 25 mg/ml	8¢† per mg	$ 13.00 – 104.00
Thorazine®(SKF brand of chlorpromazine)	300-600 mg per day	100 mg tablets bottles of 1000	5.1¢ per tab**	55.84 – 111.69
Mellaril®(Sandoz brand of thioridazine)	200-800 mg per day	100 mg tablets bottles of 1000	11.6¢ per tab**	84.68 – 338.72
Haldol®(McNeil brand of haloperidol)	5-50 mg per day	5 mg tablets bottles of 1000	20.1¢ per tab**	73.37 – 733.65
Navane®(Roerig brand of thiothixene)	20-60 mg per day	20 mg tablets bottles of 500	21.5¢ per tab**	78.48 – 235.43

*Dosage level and interval should be determined on an individual basis, in accordance with patient's response to the particular drug as well as the manufacturer's specific recommendations for the use of the product. **Based on prices listed in 1976 Red Book. †Based on Squibb list price of $9.95 per 5 ml vial.

See following page for brief summary.

PROLIXIN DECANOATE®
Fluphenazine Decanoate Injection

PROLIXIN DECANOATE®

Fluphenazine Decanoate Injection

Often works where others fail... at a fraction of the cost

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg. fluphenazine decanoate per ml. in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Physicians should be alert to the possibility that severe adverse reactions may occur which require immediate medical attention. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician experienced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal functions and blood picture should be done. Renal function of patients on long-term therapy should be monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumonias" are possible.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. These include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, and hyperreflexia; most often these are reversible, but they may be persistent. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of antiparkinsonian drugs such as benztropine mesylate or intravenous Caffeine and Sodium Benzoate Injection U.S.P., and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may have to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection U.S.P. is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package insert.

The Rape Victim

by Elaine Hilberman, M.D.

Mythologies about rape are legion. However, in recent years behavioral scientists have accumulated a body of information about rape and about an unfolding series of reactions experienced by the victim after rape. The aim of this concise, tightly reasoned book is to summarize what is now known about the needs and experiences of the victim and her family, and to provide a framework in which the clinician can more knowledgeably supply assistance and support. This document, published by the American Psychiatric Association, is the result of a project of the Association's Committee on Women.

Pointing out that the profound impact of rape stress is best understood in the context of rape as "a crime against the person and not the hymen," Dr. Hilberman sees rape as the ultimate violation of the self short of homicide, as an act of violence and humiliation in which not only is the victim's very existence threatened, and her inner and most private space invaded, but her autonomy and control are totally demolished. Dr. Hilberman shows that if and when the victim reports the crime, she is confronted with a complex series of yet additional stresses growing out of her contact with the hospital, police, courts, media and community opinion. Additionally, her crisis differs from other crises in that her usual social support system is likely to be disrupted. Her immediate needs are for empathy and safety, and a sense of control over what is happening in her dealings with the several agencies. Dr. Hilberman shows that in the absence of sensitivity to these needs, the experience of reporting becomes another assault.

This book presents a professional, sobering, and balanced picture of the problems of the rape victim and details what the clinician must know—about local hospital policy, criminal justice procedure, rape statutes, and community attitudes and services—in order to be able to treat victims with an understanding of the larger context in which rape occurs.

ELAINE HILBERMAN, M.D., *is in the Department of Psychiatry at the University of North Carolina School of Medicine.*

Medical Directors:
$40,400 — $46,700

Sr. Psychiatrists:
$35,600 — $41,100

Psychiatrists:
$28,200 — $38,800

Due to recent promotions and retirements, there are opportunities for qualified individuals to assume administrative responsibilities in psychiatric hospital settings at several locations in Ontario.

The Medical Director is accountable for developing, coordinating and directing the multidisciplinary clinical program at a given psychiatric hospital. Locations: Whitby and Brockville.

Senior Psychiatrists function as Unit Directors, administering general or specialized programs pertaining to a major segment of a hospital's population. Locations: Toronto and Penetanguishene (65 miles north of Toronto in the resort country).

Those interested in non-administrative clinical appointments are also invited to apply: Locations: As above plus other centres across Ontario.

At many locations, hospitals are affiliated with nearby universities and opportunities for joint appointments are available.

Successful applicants may choose either regular civil service appointments or renewable yearly contract at higher salary levels.

Qualifications: License to practice medicine in Ontario, with certification in psychiatry from the RCPS (Canada) or specialist standing in another jurisdiction acceptable as the equivalent of the certificate; many years responsible, appropriate experience; demonstrated ability to plan and coordinate medical services.

Please send application or resume to: **Director, File HL-01-58-77, Psychiatric Hospitals Branch, 7th Floor, 7 Overlea Blvd., Toronto, Ontario, Canada M4H 1A9**

These positions are open equally to men and women.

Ontario **Ontario Public Service**

LIBRIUM®
(chlordiazepoxide HCl)
5 mg, 10 mg, 25 mg capsules

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

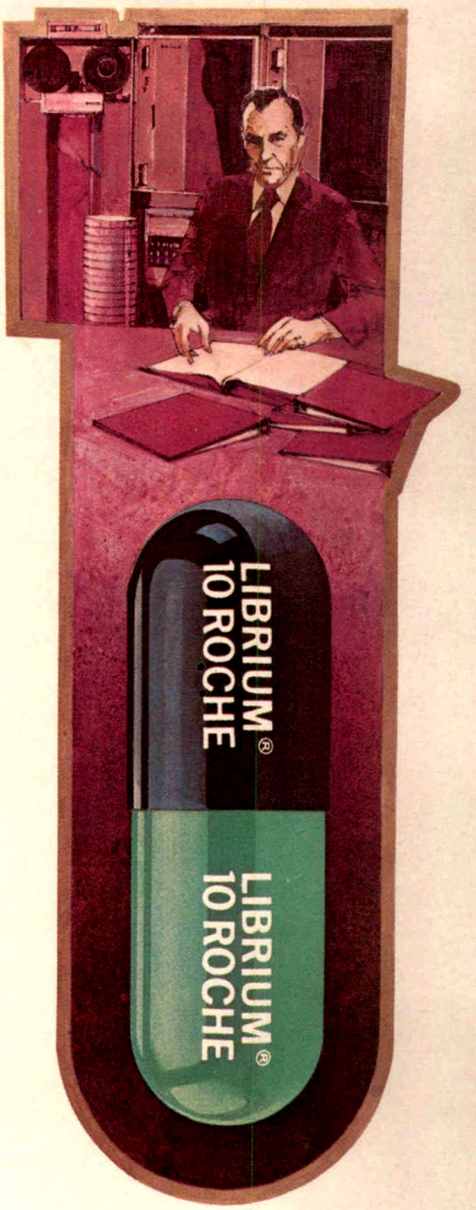
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.



ROCHE Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

AN OUTSTANDING RECORD OF SAFETY

Anxiety that obstructs the therapeutic relationship often requires adjunctive pharmacotherapy. Selecting an appropriate agent for excessively anxious patients, however, can involve considerations of safety as much as of efficacy.

Because of this, Librium® (chlordiazepoxide HCl) is often an excellent choice. One of the safest antianxiety agents available, Librium is seldom associated with serious side effects (the most common are dose-related and thus largely avoidable). Librium rarely affects the cardiovascular or respiratory systems, rarely interferes with mental acuity. However, as with all CNS-acting drugs, patients should be cautioned against driving and hazardous activities requiring complete mental alertness.

Librium efficacy is a well-documented matter of record. But, equally important, so is its highly favorable benefits-to-risk ratio.

THAT'S WHAT MAKES LIBRIUM® LIBRIUM®

a valuable link to the resources of the American Psychiatric Association

for institutions and agencies concerned with the care of the mentally disabled

Enrollment in the Hospital & Community Psychiatry Service brings multiple copies of *Hospital & Community Psychiatry* into member agencies every month, keeping staff up to date on developments and issues in the mental health field, offering new ideas and fresh perspectives, and serving as a useful resource in staff development and training programs.

Hospital & Community Psychiatry is just one of the benefits of membership in the H&CP Service. Others include a film library containing more than a hundred films specially chosen for their usefulness in staff development and community education programs; supplementary mailings of important books, reports, articles, or other material of special interest to administrators or clinicians; reduced registration fees at the annual fall Institute on Hospital & Community Psychiatry; and, on request, information and consultation from the professional staff of the American Psychiatric Association. The H&CP Service also sponsors the annual Achievement Awards competition, which gives special recognition to outstanding programs for the mentally ill and mentally retarded.

Please send me information about membership in the Hospital & Community Psychiatry Service.

A major product
announcement to psychiatrists

Introducing
Lidone™
molindone
hydrochloride
A potent
non-phenothiazine
antipsychotic agent
new from Abbott
Please see following pages
for brief summary of
prescribing information.
TM—Trademark
ABBOTT
7053195

molindone
hydrochloride

Why Lidone™ belongs among your first-line antipsychotic agents

Because of its effectiveness

Demonstrated control of target symptoms. Lidone is a non-phenothiazine antipsychotic agent, indicated for management of the manifestations of schizophrenia. As such it offers a clinically proven oral treatment effective over a broad range of target symptoms. Improvement has been reported in:

- Conceptual disorganization[1,2,6,9]
- Unusual thought content[3,4,11,12]
- Hallucinations[3,6,9,11]
- Hostility[1,10,11]
- Bizarre motor behavior[3,11,12]
- Retardation[2,8,12]

Improvement in social outlook. Lidone has enabled patients to display progress in social behavior, and improved social competence and interest.[2,7,9,12,13] Interpersonal relationships have accordingly benefited.

Because of its degree of safety

Seldom causes problem sedation. Lidone is classed among the less-sedating group of major tranquilizers. Initial drowsiness usually subsides with continued use.

Extrapyramidal effects usually controlled. These usually respond to appropriate management without cessation of drug therapy.

Significant hypotension rare; hematologic effects limited. Less than 1% incidence of significant hypotension has been reported in clinical studies, and only rare reports of leucopenia and leucocytosis.

No serious ocular effects, impotence, or excessive weight gain. Unlike some antipsychotic agents, Lidone has not been associated with these conditions.

Persistent tardive dyskinesia not reported. Only a few cases of late-occurring dyskinesia have been noted (reversible upon discontinuation of therapy), and there have been no reports of persistent tardive dyskinesia.

Other side effects comparable to other agents. See Brief Summary for a complete statement of adverse reactions.

Lidone™

molindone hydrochloride

Because of its benefits

Patients accessible to psychotherapy. Patients are seldom over-sedated with Lidone. They tend to remain alert and therefore responsive to psychotherapy and rehabilitation.

Social relationships not disrupted. Improved social behavior has been noted, and side effects which are potentially disruptive to social or family relationships (e.g., weight gain, sexual dysfunction) have not been a problem.

Permits continuity of drug therapy. Few of the side effects require discontinuation of drug therapy.

Most economical non-phenothiazine. The relatively low milligram cost and high milligram potency of molindone make it least expensive of the potent new non-phenothiazine antipsychotics, and also less costly than many leading phenothiazines.[14]

Unique alternative for refractory patients. Molindone is unrelated to other antipsychotic drug families. Hence Lidone may benefit patients who are unresponsive to, or who cannot tolerate, other agents.

Please see following page for brief summary of prescribing information.

Because of its ease of administration

Simple Oral Regimen according to severity of presenting symptoms:

Dose strength	Schizophrenic manifestations	Dosage regimen
5 mg	mild	5 mg three or four times daily. (An increase to 15 mg three or four times daily may be required).
10 mg	moderate	10 mg three or four times daily. (An increase to 25 mg three or four times daily may be required.)
25 mg	severe	Daily dosage as high as 225 mg may be required.

Dosage Comparison at approximately equipotent dose levels:

Agent	Comparable doses[14]
Chlorpromazine	100 mg
Thioridazine	100 mg
Lidone	10 mg
Trifluoperazine	5 mg
Thiothixene	3 mg*
Haloperidol	2 mg
Fluphenazine	2 mg*

*Product not supplied in this exact strength.

Supplied in bottles of 100 capsules

Dose strength	Drug code	Color
5 mg	NDC 0074-5542-13	blue and cream
10 mg	NDC 0074-5543-13	red and cream
25 mg	NDC 0074-5544-13	brown and cream

7053195

Brief summary of prescribing information for

Lidone™ (molindone hydrochloride)

DESCRIPTION — LIDONE (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

LIDONE is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4(5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

ACTIONS — LIDONE (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditional response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, LIDONE antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, LIDONE exerts its effect on the ascending reticular activating system.

Human metabolic studies show LIDONE (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24 to 36 hours. There are 36 recognized metabolites with less than 2 to 3% unmetabolized LIDONE being excreted in urine and feces.

INDICATIONS — LIDONE (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS — LIDONE (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy: Studies in pregnant patients have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats oral dose —
20 mg/kg/day — 2 weeks, no adverse effect
40 mg/kg/day — 2 weeks, no adverse effect

Pregnant Mice oral dose —
20 mg/kg/day — 9 days, slight increase resorptions
40 mg/kg/day — 9 days, slight increase resorptions

Pregnant Rabbits oral dose —
5 mg/kg/day — 12 days, no adverse effect
10 mg/kg/day — 12 days, no adverse effect
20 mg/kg/day — 12 days, no adverse effect

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of LIDONE (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of LIDONE (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

PRECAUTIONS — Some patients receiving LIDONE (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving LIDONE. Caution should be exercised where increased activity may be harmful.

LIDONE does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, convulsive seizures have been reported in a few instances.

LIDONE has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS

CNS Effects — The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological Extrapyramidal Reactions — Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia — Motor restlessness may occur early.

Parkinson Syndrome — Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome — Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System — Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological — There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with LIDONE may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects — Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Lactation associated with LIDONE therapy has not been reported. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with LIDONE.

Cardiovascular — Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological — Lens opacities and pigmentary retinopathy have not been reported where patients have received LIDONE (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with LIDONE.

Skin — Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with LIDONE usage alone.

LIDONE (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when LIDONE is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia — Although rarely reported with LIDONE (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION — Initial and maintenance doses of LIDONE (molindone hydrochloride) should be individualized, and the minimal effective dose should be employed. Elderly and debilitated patients should be started on lower dosage.

DOSAGE SCHEDULE, BASED ON SEVERITY OF SYMPTOMATOLOGY

1. Mild — 5 mg three or four times a day; an increase to 15 mg three or four times a day may be required.
2. Moderate — 10 mg three or four times a day; an increase to 25 mg three or four times a day may be required.
3. Severe — daily dosage as high as 225 mg may be required.

DRUG INTERACTIONS — Potentiation of drugs administered concurrently with LIDONE (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when LIDONE is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE — Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of LIDONE (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of LIDONE (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by LIDONE in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized LIDONE from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of LIDONE is excreted unmetabolized in the urine.) However, poor response of the patient may justify use of these procedures.

While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized LIDONE in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents (i.e., Artane*, Cogentin*, Akineton*).

Where The Action Is—

For more than a decade the general hospital psychiatric unit has been the principal locus of inpatient treatment. This latest Joint Information Service national survey brings up to date its earlier—and the original—study of this important component of the psychiatric scene. It reveals that the remarkable rate of growth held up, showing an increase of 50 percent in the number of units between 1963 and 1971, and an increase of 46 percent in the number of admissions. And it verifies that general hospital psychiatry has become increasingly comprehensive, with an impressively high level of outpatient service, emergency service, and even consultation to community agencies. Indeed, the general hospital accounts for several times as much service and activity as the widely heralded federally supported community mental health center.

This study also involves the private psychiatric hospitals, which have not changed much in number but are admitting about 10,000 more patients than in 1964—and they, too, are providing a remarkably comprehensive program.

It's your responsibility to be well-informed about these extraordinarily significant and vital pieces of American psychiatric service. You can do so by sending the order form below.

Tranxene® IV CAPSULES SINGLE DOSE TABLETS

CLORAZEPATE DIPOTASSIUM 4306CB **Brief Summary**

ACTIONS—Pharmacologically, TRANXENE (clorazepate dipotassium) has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine.

INDICATIONS—TRANXENE is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of TRANXENE for long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS—TRANXENE is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS—TRANXENE is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on TRANXENE should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since TRANXENE has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, TRANXENE is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:

Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:

TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS—In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on TRANXENE for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS—The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION—

For symptomatic relief of anxiety:

TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose daily at bedtime; the recommended initial dose is 15 mg. After the initial dose, the response of the patient may require adjustment of subsequent dosage. Lower doses may be indicated in the elderly patient. Drowsiness may occur at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single dose every 24 hours. This tablet is intended as an alternate dosage form for the convenience of patients stabilized on a dose of 7.5 mg. capsules three times a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be administered as a single dose every 24 hours.

For symptomatic relief of acute alcohol withdrawal:

Recommended schedule: 1st 24 hours, 30 mg TRANXENE initially, followed by 30 to 60 mg in divided doses; 2nd 24 hours, 45 to 90 mg in divided doses; 3rd 24 hours, 22.5 to 45 mg in divided doses; 4th day, 15 to 30 mg in divided doses. Thereafter gradually reduce to 7.5 to 15 mg daily, and discontinue as soon as condition is stable. Maximum daily dose is 90 mg. Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS—If TRANXENE is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. Animal experience indicates that TRANXENE prolongs the sleeping time after hexobarbital or after ethyl alcohol, increases the inhibitory effects of chlorpromazine, but does not exhibit monoamine oxidase inhibition. Clinical studies have shown increased sedation with concurrent hypnotic medications. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If TRANXENE (clorazepate dipotassium) is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

MANAGEMENT OF OVERDOSAGE—Overdosage is usually manifested by varying degrees of CNS depression ranging from slight sedation to coma. As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatment of overdosage should consist of the general measures employed in the management of overdosage of any CNS depressant. Gastric evacuation either by the induction of emesis, lavage, or both, should be performed immediately. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though rarely reported, may occur with large overdoses. In such cases the use of agents such as Levophed® (levarterenol) or Aramine® (metaraminol) should be considered.

While reports indicate that individuals have survived overdoses of TRANXENE as high as 450 to 675 mg., these doses are not necessarily an accurate indication of the amount of drug absorbed, since the time interval between ingestion and the institution of treatment was not always known. Sedation in varying degrees was the most common physiological manifestation of TRANXENE overdosage. Deep coma when it occurred was usually associated with the ingestion of other drugs in addition to TRANXENE.

CLINICAL PHARMACOLOGY—Studies in healthy men have shown that TRANXENE has depressant effects on the central nervous system. Prolonged administration of single daily doses as high as 120 mg. was without toxic effects. Abrupt cessation of high doses was followed in some patients by nervousness, insomnia, irritability, diarrhea, muscle aches, or memory impairment.

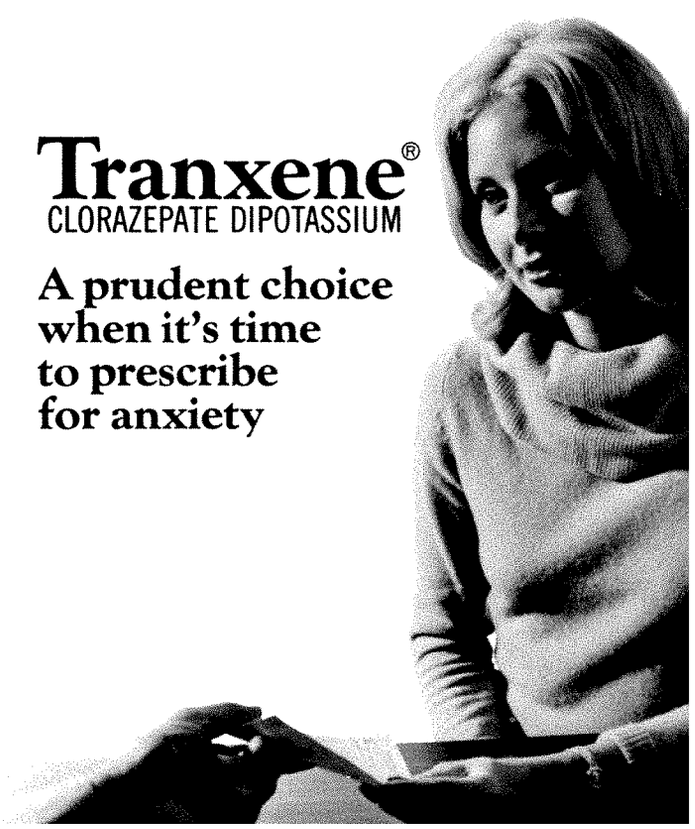
Absorption–Excretion:

After oral administration of TRANXENE, there is essentially no circulating parent drug. Nordiazepam, its primary metabolite, quickly appears in the blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-TRANXENE, about 80% was recovered in the urine and feces within 10 days. Excretion was primarily in the urine with about 1% excreted per day on day 10.

HOW SUPPLIED—TRANXENE (clorazepate dipotassium) is supplied as capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 (NDC 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).

7.5 mg. capsules (gray with maroon cap) in bottles of 100 (NDC 0074-3418-13) and 500 (NDC 0074-3418-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3418-11).



15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) and 500 (NDC 0074-3419-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage strengths:

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in bottles of 100 (NDC 0074-2699-13).

7043191/R

A prudent prescription for today's anxious patient

A different tranquilizer. Times change. Today's patient has changed. And the physician's most prudent choice of therapy for anxious patients may also change. Thus if you are now thinking about changing your choice of minor tranquilizers, consider Tranxene.

A change of look. Tranxene is a physically distinctive change of therapy. It's very different in form and appearance from any other tranquilizers your patients have previously received or seen.

Greater versatility. Its added dosage options are different too. They permit not only conventional divided doses, but also convenient once-a-day regimens . . . including an ultrasimple single dose tablet (11.25 mg) especially suited to elderly patients.

Yet the same effectiveness. Prescribe with confidence. In numerous published studies involving hundreds of patients, Tranxene has been shown to be clinically equivalent to diazepam in treating anxiety.

Tranxene® 4306CB C IV
CLORAZEPATE DIPOTASSIUM

Maybe it's time?

UNIVERSITY COLLEGE OF MEDICINE
LIBRARY

Basic tool of primitive psychiatry

Fertility protective statues: For pregnant women, the statues insured a healthy, beautiful child, and protected both mother and child from the "evil eye." For sterile women, the statues' magical power aided fertility. Ashanti, Ghana.

From the collection of the Segy Gallery, New York City. Reproduced with permission.

Basic tool of modern psychiatry

Thorazine®

brand of **chlorpromazine**

Tablets: 25 and 50 mg of the HCl

- Effective control of psychotic symptoms
- Especially useful in agitated, violent or anxious schizophrenic patients
- Unsurpassed clinical experience
- 18 convenient dosage forms and strengths

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings:

Caution is recommended when 'Thorazine' is administered for the treatment of vomiting in children.

Antiemetics are not recommended to treat uncomplicated short-term vomiting in children or vomiting of unknown etiology.

The possibility of extrapyramidal reactions from 'Thorazine' may confuse the diagnosis of Reye's syndrome or other encephalopathy. Although unconfirmed, some suspicion exists that centrally-acting antiemetics may contribute to or adversely affect the course of Reye's syndrome, and should be avoided in suspected cases.

©1967, 1968, 1969 SmithKline Corporation

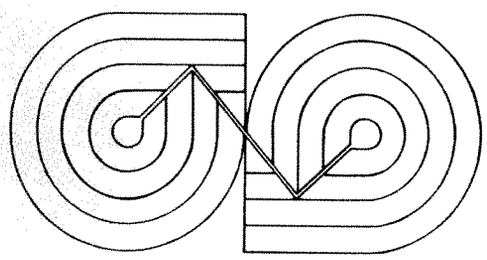
Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudoparkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.



NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; Single Unit Packages of 100 (intended for institutional use only). Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only). Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg. Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit 3 copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later. Annual meeting papers should not be submitted to the *Journal* until *after* the annual meeting.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

All communications about a manuscript should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; with other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, the copyright of all parts of the paper, including any illustrations, passes from the author to the *Journal*. Written permission to reprint material published in the *Journal* must first be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for this permission.

Informed consent. Manuscripts that report the results of experimental investigation on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure had been fully explained.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

SPECIFICATIONS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond paper. **All parts of the manuscript** (including case reports, footnotes, references, etc.) **should be double spaced,** with margins of 2½-3¾ cm (1-1½ inches) at the top, bottom, and both sides. Subheads should be inserted at reasonable intervals. All abbreviations should be explained. All measurements must be in metric units.

Length. All pages of the manuscript must be numbered, including references, tables, and figures. The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles: 3,800 words or the equivalent including references, tables, and figures (about 15 manuscript pages). Brief Communications: 2,500 words or the equivalent (about 10 manuscript pages); see stipulations above. Clinical and Research Reports: 1,000 words, 10 references, 1 table. Letters to the Editor: 500 words. Please write the total number of words and the number of tables and figures on the title page of the submitted material.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the coauthor who has been designated to assume responsibility for the paper and reprint requests. Authors named in the by-line should be limited to principal researchers and writers; other collaborators may be acknowledged in a footnote.

Precis. A brief precis (60–100 words for regular articles, 40–60 words for Brief Communications) is included at the beginning of each article. The author may prepare the precis or ask that the *Journal* staff prepare it.

References. References should be typed **double spaced** on a separate sheet of paper. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Tables and figures should be self-explanatory and should supplement, not duplicate, text. See recent issues of the *Journal* for general style.

Each table should be typed double spaced on a separate sheet attached at the end of the manuscript. Columns of like material should read down, not across.

One complete set of figures, in the form of glossy prints, should be submitted. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Graphs should be finished drawings not requiring further artwork. Authors are urged to engage professional assistance in the preparation of figures and may be charged for any further artwork that must be done in the editorial office.

AUTHORS CORRECTIONS

After the paper has been scheduled for publication, the edited manuscript will be sent to the first-named author for corrections and answers to queries. Prompt return is necessary. If an author expects to be away from his office for a long period of time after being notified of the acceptance of his paper, he should inform the *Journal* office or arrange with a coauthor to assume responsibility for the paper. Galley proofs will not be sent to authors.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Requests from others to order reprints should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

Hallucinations and delusions rapidly controlled

Trapped by unrealistic perceptions...

...and terrified by his hallucinations and delusions on admission. Because Navane (thiothixene) is particularly effective in controlling these symptoms and their resulting suspiciousness and anxiety, it can provide the essential first step toward restoring stabilization and facilitating the development of purposeful activity. Extensive clinical data and widespread experience confirm the effectiveness of Navane in rapidly controlling such typical psychotic behavior on admission.

Long-term therapy is facilitated...

...because Navane offers an unsurpassed safety record among effective neuroleptic agents, permitting continuing control of symptoms of psychoses such as hallucinations and delusions. Like other antipsychotic agents, extrapyramidal symptoms may occur, but are readily controlled through dosage adjustments or antiparkinsonian agents. Cardiovascular effects such as hypotension, and hepatic or hematopoietic effects rarely occur and are generally mild and transient, with no jaundice or agranulocytosis reported to date.

An effective first step towards discharge...

Navane®

(thiothixene) (thiothixene HCl)

Capsules 1 mg., 2 mg., 5 mg., 10 mg., 20 mg. Concentrate 5 mg./ml.—Intramuscular 2 mg./ml.

For prescribing information, including adverse reactions and contraindications, please see following page of this advertisement.

ROERIG Pfizer

New York, New York 10017

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Actions. Navane is a psychotropic agent of the thioxanthene series. Navane possesses certain chemical and pharmacological similarities to the piperazine phenothiazines and differences from the aliphatic group of phenothiazines. Navane's mode of action has not been clearly established.

Indications. Navane is effective in the management of manifestations of psychotic disorders.

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy* – Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children–The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration – As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane. Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudoparkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leucocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution–For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate–In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor elevating action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg, of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% w/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

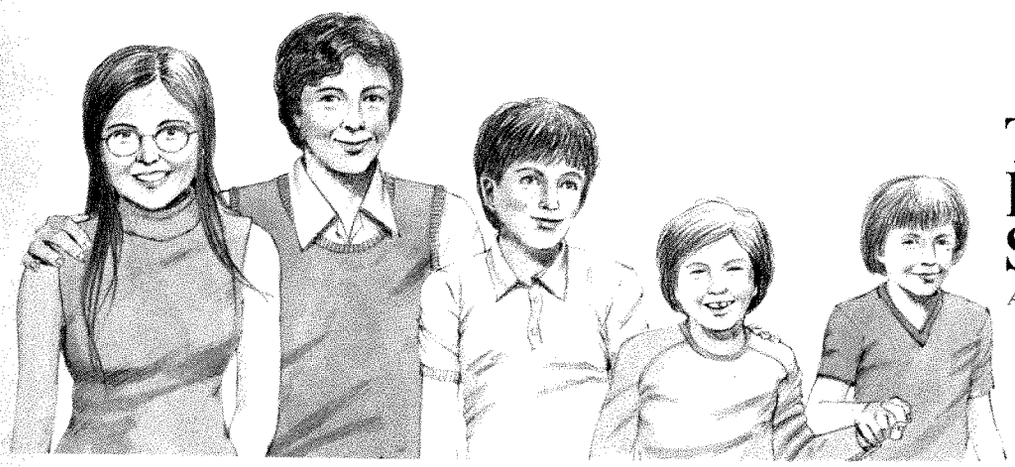
Flexibility is our forte: The Brown Schools

Because we maintain great flexibility at all three of our treatment centers, each resident follows an individualized plan of treatment, training, education and care prescribed for that resident alone.

And we believe that residential treatment conducted in this highly individualized manner still is the most effective treatment for many. Our large, experienced staff is skilled in the treatment of children, adolescents and adults with learning disabilities, neurological impairment, mental retardation or emotional disturbance.



Our three treatment centers are geographically separated to provide the appropriate residential milieu, yet close enough that residents benefit from the comprehensive training and expertise of the entire staff. All three are psychiatrically oriented, so that we are prepared to treat emotional disturbance in persons of any intellectual capacity and of any age.

The vulnerable ages

The first epileptic seizure is most likely to occur during early childhood and at the onset of puberty

About 9 out of 10 epileptics experience their first seizure before the age of 20—with the highest incidence between 5 and 7, when children start school, and at the onset of puberty, a time of physiological and psychic turmoil.[1] The most common type, grand mal, occurs in approximately 75% of epileptic children,[1] and more than 50% of patients who suffer initially from petit mal develop grand mal seizures before they reach the age of 16.[2]

Mysoline (primidone) for control of grand mal, psychomotor and focal epilepsy

At the onset and afterwards — used alone or as concomitant therapy, MYSOLINE may reduce the frequency and severity of major motor seizures—or even eliminate them. *Excellent* for control of grand mal. Valuable for control of psychomotor[1,3,4] and focal epilepsy as well.[5]

Add Mysoline when control with other anticonvulsants is inadequate — As concomitant therapy, MYSOLINE can improve seizure control in grand mal and psychomotor epilepsy. The combined use of phenobarbital, diphenylhydantoin, and MYSOLINE may have additive anticonvulsant effects without additive side effects.[6]

Change to Mysoline when other anticonvulsants fail — A changeover to MYSOLINE is frequently warranted when other anticonvulsants must be discontinued because of important side effects, or when grand mal seizures are refractory to phenobarbital, with or without diphenylhydantoin.[7]

Mysoline® (primidone)

may be the start of a better life for the epileptic

initial and maintenance therapy for
grand mal, psychomotor and focal epilepsy

BRIEF SUMMARY
(For full prescribing information, see package circular.)

MYSOLINE® Brand of PRIMIDONE
Anticonvulsant

ACTIONS: MYSOLINE acts on the central nervous system to raise seizure threshold or alter seizure pattern. The mechanism(s) of action of anticonvulsant drugs is not known.

Primidone has anticonvulsant activity *per se*. In addition, its two metabolites possess anticonvulsant qualities. The major metabolite is phenylethylmalonamide (PEMA); the other is phenobarbital. In addition to its own anticonvulsant potential, PEMA potentiates phenobarbital.

INDICATIONS: MYSOLINE, either alone or used concomitantly with other anticonvulsants, is indicated in the control of grand mal, psychomotor, and focal epileptic seizures. It may control grand mal seizures refractory to other anticonvulsant therapy.

CONTRAINDICATIONS: Primidone is contraindicated in: 1) patients with porphyria and 2) patients who are hypersensitive to phenobarbital (see ACTIONS).

WARNINGS: The abrupt withdrawal of antiepileptic medication may precipitate status epilepticus.

The therapeutic efficacy of a dosage regimen takes several days before it can be assessed.

Use in pregnancy: Recent reports strongly suggest an association between the use of anticonvulsant drugs by women with epilepsy and an elevated incidence of birth defects in children born to these women. Reference has been made to primidone in several cases in which it was used *in combination* with other anticonvulsants; but its teratogenicity has not been conclusively demonstrated. The possibility exists that other factors, *e.g.*, genetic factors or the epileptic condition, may contribute to the higher incidence of birth defects. The data also indicate that the great majority of mothers receiving anticonvulsant medication deliver normal infants.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and risk to both mother and the unborn child.

When the nature, frequency, and severity of the seizures do not pose a clear threat to the patient, good medical practice requires that the physician weigh the expected therapeutic benefit of anticonvulsant therapy against possible risk on an individual basis.

Neonatal hemorrhage, with a coagulation defect resembling vitamin K deficiency, has been described in newborns whose mothers were taking primidone and other anticonvulsants. Pregnant women under anticonvulsant therapy should receive prophylactic vitamin K_1 therapy for one month prior to, and during, delivery.

The physician should weigh all of the foregoing considerations when treating and counseling epileptic women of childbearing potential.

PRECAUTIONS: The total daily dosage should not exceed 2 Gm. Since MYSOLINE therapy generally extends over prolonged periods, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

In nursing mothers: There is evidence that in mothers treated with primidone, the drug appears in the milk in substantial quantities. Since tests for the presence of primidone in biological fluids are too complex to be carried out in the average clinical laboratory, it is suggested that the presence of undue somnolence and drowsiness in nursing newborns of MYSOLINE-treated mothers be taken as an indication that nursing should be discontinued.

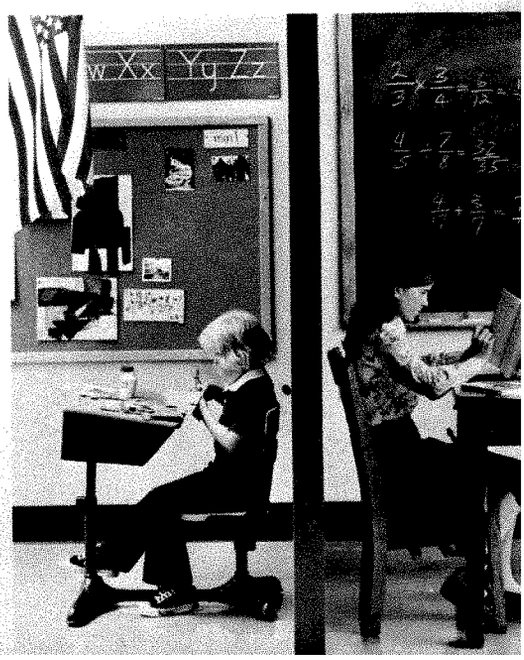
ADVERSE REACTIONS: The most frequently occurring early side effects are ataxia and vertigo. These tend to disappear with continued therapy, or with reduction of initial dosage. Occasionally, the following have been reported: nausea, anorexia, vomiting, fatigue, hyperirritability, emotional disturbances, sexual impotency, diplopia, nystagmus, drowsiness, and morbilliform skin eruptions. Occasionally, persistent or severe side effects may necessitate withdrawal of the drug. Megaloblastic anemia may occur as a rare idiosyncrasy to MYSOLINE and to other anticonvulsants. The anemia responds to folic acid, 15 mg. daily, without necessity of discontinuing medication.

DOSAGE AND ADMINISTRATION: The average adult dose is 0.75 to 1.5 Gm. per day. The initial dose is 250 mg. Increments of 250 mg. are added, usually at weekly intervals, to tolerance, or therapeutic effectiveness, up to daily doses not exceeding 2.0 Gm. A typical dosage schedule for the introduction of MYSOLINE (primidone) is as follows:

Adults and Children Over 8 Years of Age

1st Week 250 mg. daily at bedtime	*2nd Week* 250 mg. b.i.d.
3rd Week 250 mg. t.i.d.	*4th Week* 250 mg. q.i.d.

In children under 8 years of age, maintenance levels are established by a similar schedule, but at one-half the adult dosage. It is best to begin with 125 mg., with gradual weekly increases of 125 mg. a day, to a daily total usually between 500 mg. and 750 mg.



In patients already receiving other anticonvulsants: MYSOLINE should be gradually increased as dosage of the other drug(s) is maintained or gradually decreased. This regimen should be continued until satisfactory dosage level is achieved for combination, or the other medication is completely withdrawn. When therapy with this product alone is the objective, the transition should not be completed in less than two weeks.

MYSOLINE 50 mg. Tablet can be used to practical advantage when small fractional adjustments (upward or downward) may be required, as in the following circumstances:

- for initiation of combination therapy
- during "transfer" therapy
- for added protection in periods of stress or stressful situations that are likely to precipitate seizures (menstruation, allergic episodes, holidays, etc.)

HOW SUPPLIED: MYSOLINE *Tablets*—No. 430—Each tablet contains 250 mg. of primidone (scored), in bottles of 100 and 1,000. Also in unit dose package of 100. No. 431—Each tablet contains 50 mg. of primidone (scored), in bottles of 100 and 500. MYSOLINE *Suspension*—No. 3850—Each 5 cc. (teaspoonful) contains 250 mg. of primidone, in bottles of 8 fluid ounces.

BOOKS IN PSYCHIATRY AND RELATED DISCIPLINES

BIOLOGICAL BASES OF PSYCHIATRIC DISORDERS

Edited by **Alan Frazer, Ph.D.**, and **Andrew Winokur, M.D., Ph.D.**

An interdisciplinary venture into the mind and the sources of its disorders, this text explores the intricate relationship between the brain as a biological entity and human behavior. Integrating contributions from anatomy, biology, pharmacology, physiology, neuroendocrinology, genetics, psychology and psychiatry, it illustrates the fruitful partnership of basic and clinical investigations in solving practical problems and in framing fundamental questions. Based on a carefully planned biological background, it deals with substantive issues in the major behavior disorders.

1977 xii + 286pp., illus. (7"x10") $15.00

DEPRESSION AND SCHIZOPHRENIA: A Contribution on their Chemical Pathologies

By **H.M. van Praag, M.D., Ph.D.**

The focus is on the interrelations between disturbed cerebral function and disturbed behavior. Dr. van Praag puts forth hypotheses which, although largely derived from animal experiments, can now be clinically tested. The book summarizes and weighs the merits of work done in the last 15 years concerning the relationship between disturbed behavior and monoamines. Separate sections deal with the diagnosis of depression and of schizophrenia, and with the significance of central monoamine metabolism in these syndromes' occurrence. Intended for those interested in the biological determinants of and treatment methods for disturbed human behavior.

1977 xiv + 260pp., illus. $20.00

PSYCHIATRY: AREAS OF PROMISE AND ADVANCEMENT

Edited by **John Paul Brady, M.D., Joe Mendels, M.D., Martin T. Orne, M.D., Ph.D.**, and **Wolfram Rieger, M.D.**

Beginning with a brief historical account of 200 years of American psychiatry, contributions trace advancements in, and project the future for, such areas of study as: psychobiology of schizophrenia, depression and addiction; adrenergic responses in the affective disorders; psychosurgery; psychopathology and psychopharmacology; consultation psychiatry. The book traces the trend toward establishing a scientific foundation through emphasis on rational scientific investigation of behavioral disorders and their psychological and biological correlates.

1977 xiv + 253pp., illus. $15.00

PHARMACOKINETICS OF PSYCHOACTIVE DRUGS: Blood Levels and Clinical Response

Edited by **Louis A. Gottschalk, M.D.**, and **Sidney Merlis, M.D.**

This book describes the measurement problems involved in the pharmacological assay of psychoactive drugs and offers innovative and expert approaches to solving these problems. *"... a must for any serious student of pharmacokinetics."—Am J Pharm Ed*

1976 xvi + 256pp., illus. $20.00

AGING AND DEMENTIA

Edited by **W. Lynn Smith, Ph.D.**, and **Marcel Kinsbourne, D.M.**

Contents: Dementia of Old Age (Wang); Morphological Changes and Dementia in Old Age (Tomlinson); The Radiographic Morphology of Cerebral Atrophy (Pear); Vascular Disease and Dementia in the Elderly (O'Brien); Transmissible Virus Dementia: The Relation of Transmissible Spongiform Encephalopathy to Creutzfeldt–Jakob Disease (Traub, Gajdusek, Gibbs, Jr.); Intellect and Personality in the Aged (Savage); Cognition in Dementia Presenilis (Haward); Future Perspectives in Aging and Dementia (Nay); Cognitive Decline with Advancing Age: An Interpretation (Kinsbourne).

1977 xii + 244pp., illus. $15.00

PATHOGENESIS AND TREATMENT OF HEADACHE

Edited by **Otto Appenzeller, M.D., Ph.D.**

All types of headache discussed from several viewpoints, including ENT, ophthalmology and neurosurgery. Both the art of treatment and the scientific basis of therapy are considered in such contributions as: An Approach to the Patient with Headache (Friedman); Psychogenic Headache and its Treatment, Including Biofeedback Techniques (Diamond); Neurosurgical Aspects of Head Pain (Walker); Migraine (Friedman); Cluster Headache (Graham); Headaches in Children (Atkinson); Disorders of Immune Mechanisms and Headache (Dalessio). An up-to-date review of current knowledge.

1976 x + 217pp., illus. $18.00

PHENOMENOLOGY AND TREATMENT OF DEPRESSION

Edited by **William E. Fann, M.D., Ismet Karacan, M.D., D.Sc., Alex D. Pokorny, M.D.**, and **Robert L. Williams, M.D.**

Concerned with the etiology, diagnosis and treatment of clinical depression, this book presents biological and psychodynamic theories reflecting recent research and clinical experience. Included among topics reviewed and analyzed are: endocrinological and biogenic amine questions; electroconvulsive therapy, novel hospital modalities, crisis intervention techniques and outpatient care; medication regimens. Diagnostic techniques are discussed by experts, as are suicide, sociological and environmental issues.

1977 xviii + 350pp., illus. $20.00

PSYCHOTROPIC ACTION OF HORMONES

Edited by **Turan M. Itil, M.D., Gerhard Laudahn, M.D.**, and **Werner M. Herrmann, M.D.**

This book deals with the relationship between hormones and human behavior, especially with regard to the potential for hormone therapy in alleviating certain psychopathological conditions.

1976 xvi + 248pp., illus. $20.00

Haldol® (haloperidol)

tablets/concentrate/injection

For long-term control of psychotic symptoms with minimal risk of toxicity

A Dosage Form for Every Need:

5 tablet strengths for convenience in individualizing dosage: ½ mg., 1 mg., 2 mg., 5 mg. and 10 mg.

A tasteless, odorless, colorless liquid concentrate for better patient acceptability: 2 mg. per ml.

A rapid-acting injection for psychiatric emergencies: 5 mg. per ml., with 1.8 mg. methylparaben and 0.2 mg. propylparaben per ml., and lactic acid for pH adjustment to 3.4±0.2.

Indications: HALDOL haloperidol is indicated for use in the management of manifestations of psychotic disorders.

It is also indicated for the control of tics and vocal utterances of Gilles de la Tourette's syndrome.

Contraindications: HALDOL haloperidol is contraindicated in patients who are severely depressed, comatose, have CNS depression due to alcohol or other centrally-acting depressants, have Parkinson's disease or are hypersensitive to this drug.

Warnings: ***Usage in Pregnancy:*** Safe use of HALDOL haloperidol in pregnancy and lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the possible benefits of the drug be weighed against the potential hazards. A case of phocomelia in an infant whose mother received haloperidol along with a number of other medications during the first trimester of pregnancy has been reported (a causal relationship was not established in this case). Animals receiving 2 to 20 times the maximum human dose of haloperidol orally and/or parenterally showed increased incidence of resorption, reduced fertility, delayed delivery, dose-related pup mortality (presumably due to lack of maternal care reflecting CNS depression).

Usage in Children: Safety and effectiveness in children have not been established; therefore, this drug is not recommended for use in the pediatric age group.

General: Cases of bronchopneumonia, some fatal, have followed the use of major tranquilizers, including haloperidol. It has been postulated that lethargy and decreased sensation of thirst may lead to dehydration, hemoconcentration and reduced pulmonary ventilation. If these signs and symptoms appear, especially in the elderly, the physician should institute remedial therapy promptly. Although not reported with HALDOL haloperidol, decreased serum cholesterol and/or cutaneous and ocular changes have been reported in patients receiving chemically-related drugs. HALDOL haloperidol may impair the mental and/or physical abilities required for the performance of hazardous tasks such as operating machinery or driving a motor vehicle. The ambulatory patient should be warned accordingly. The use of alcohol should be avoided due to possible additive effects and hypotension.

Precautions: HALDOL haloperidol should be administered cautiously to patients: (1)—with severe cardiovascular disorders, because of the possibility of transient hypotension and/or precipitation of anginal pain. Should hypotension occur and a vasopressor be required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur. (2)—receiving anticonvulsant medication, because HALDOL haloperidol may lower the convulsive threshold. Adequate anticonvulsant therapy should be maintained concomitantly. (3)—with known allergies, or with a history of allergic reactions to drugs. (4)—receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione).

If concomitant antiparkinson medication is required, it may have to be continued after HALDOL haloperidol is discontinued because of the difference in excretion rates. If both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson agents, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used to control mania in cyclic disorders there may be a rapid mood swing to depression.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions*—Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which usually were mild to moderately severe and reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Administration of antiparkinson drugs may be required for control of such reactions. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Persistent Tardive Dyskinesia*—Tardive dyskinesia may appear during long-term therapy or after therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear irreversible. There is no known effective treatment. All antipsychotic agents should be discontinued. The syndrome may be masked by reinstitution of drug, increasing dosage, or switching to a different antipsychotic agent. *Other CNS Effects*—Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations. ***Cardiovascular Effects:*** Tachycardia and hypotension. ***Hematologic Effects:*** Reports have appeared of mild and usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis. Agranulocytosis has rarely been reported and then only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice have been reported, although a causal relationship has not been established. ***Dermatologic Reactions:*** Maculopapular and acneiform skin reactions and isolated cases of photosensitivity and loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

Complete dosage information available in insert which accompanies each package (or on request).

The use of the injectable form is intended for the acutely agitated psychotic patient with moderately severe to very severe symptoms.

IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed. 9-74

McNEIL McNeil Laboratories, Inc.
Fort Washington, Pa. 19034

Haldol®
(haloperidol)
tablets/concentrate/injection

For long-term control with minimal risk of toxicity

Highly effective in a wide range of psychotic symptoms,[1-7]
such as hallucinations, delusions, suspiciousness, hostility, mania, psychomotor agitation, etc., in both acute and chronic disorders.

Usually leaves patients relatively alert and responsive...[1-3]
better able to cope with job and family responsibilities...as well as easier to reach with supportive and rehabilitative measures.

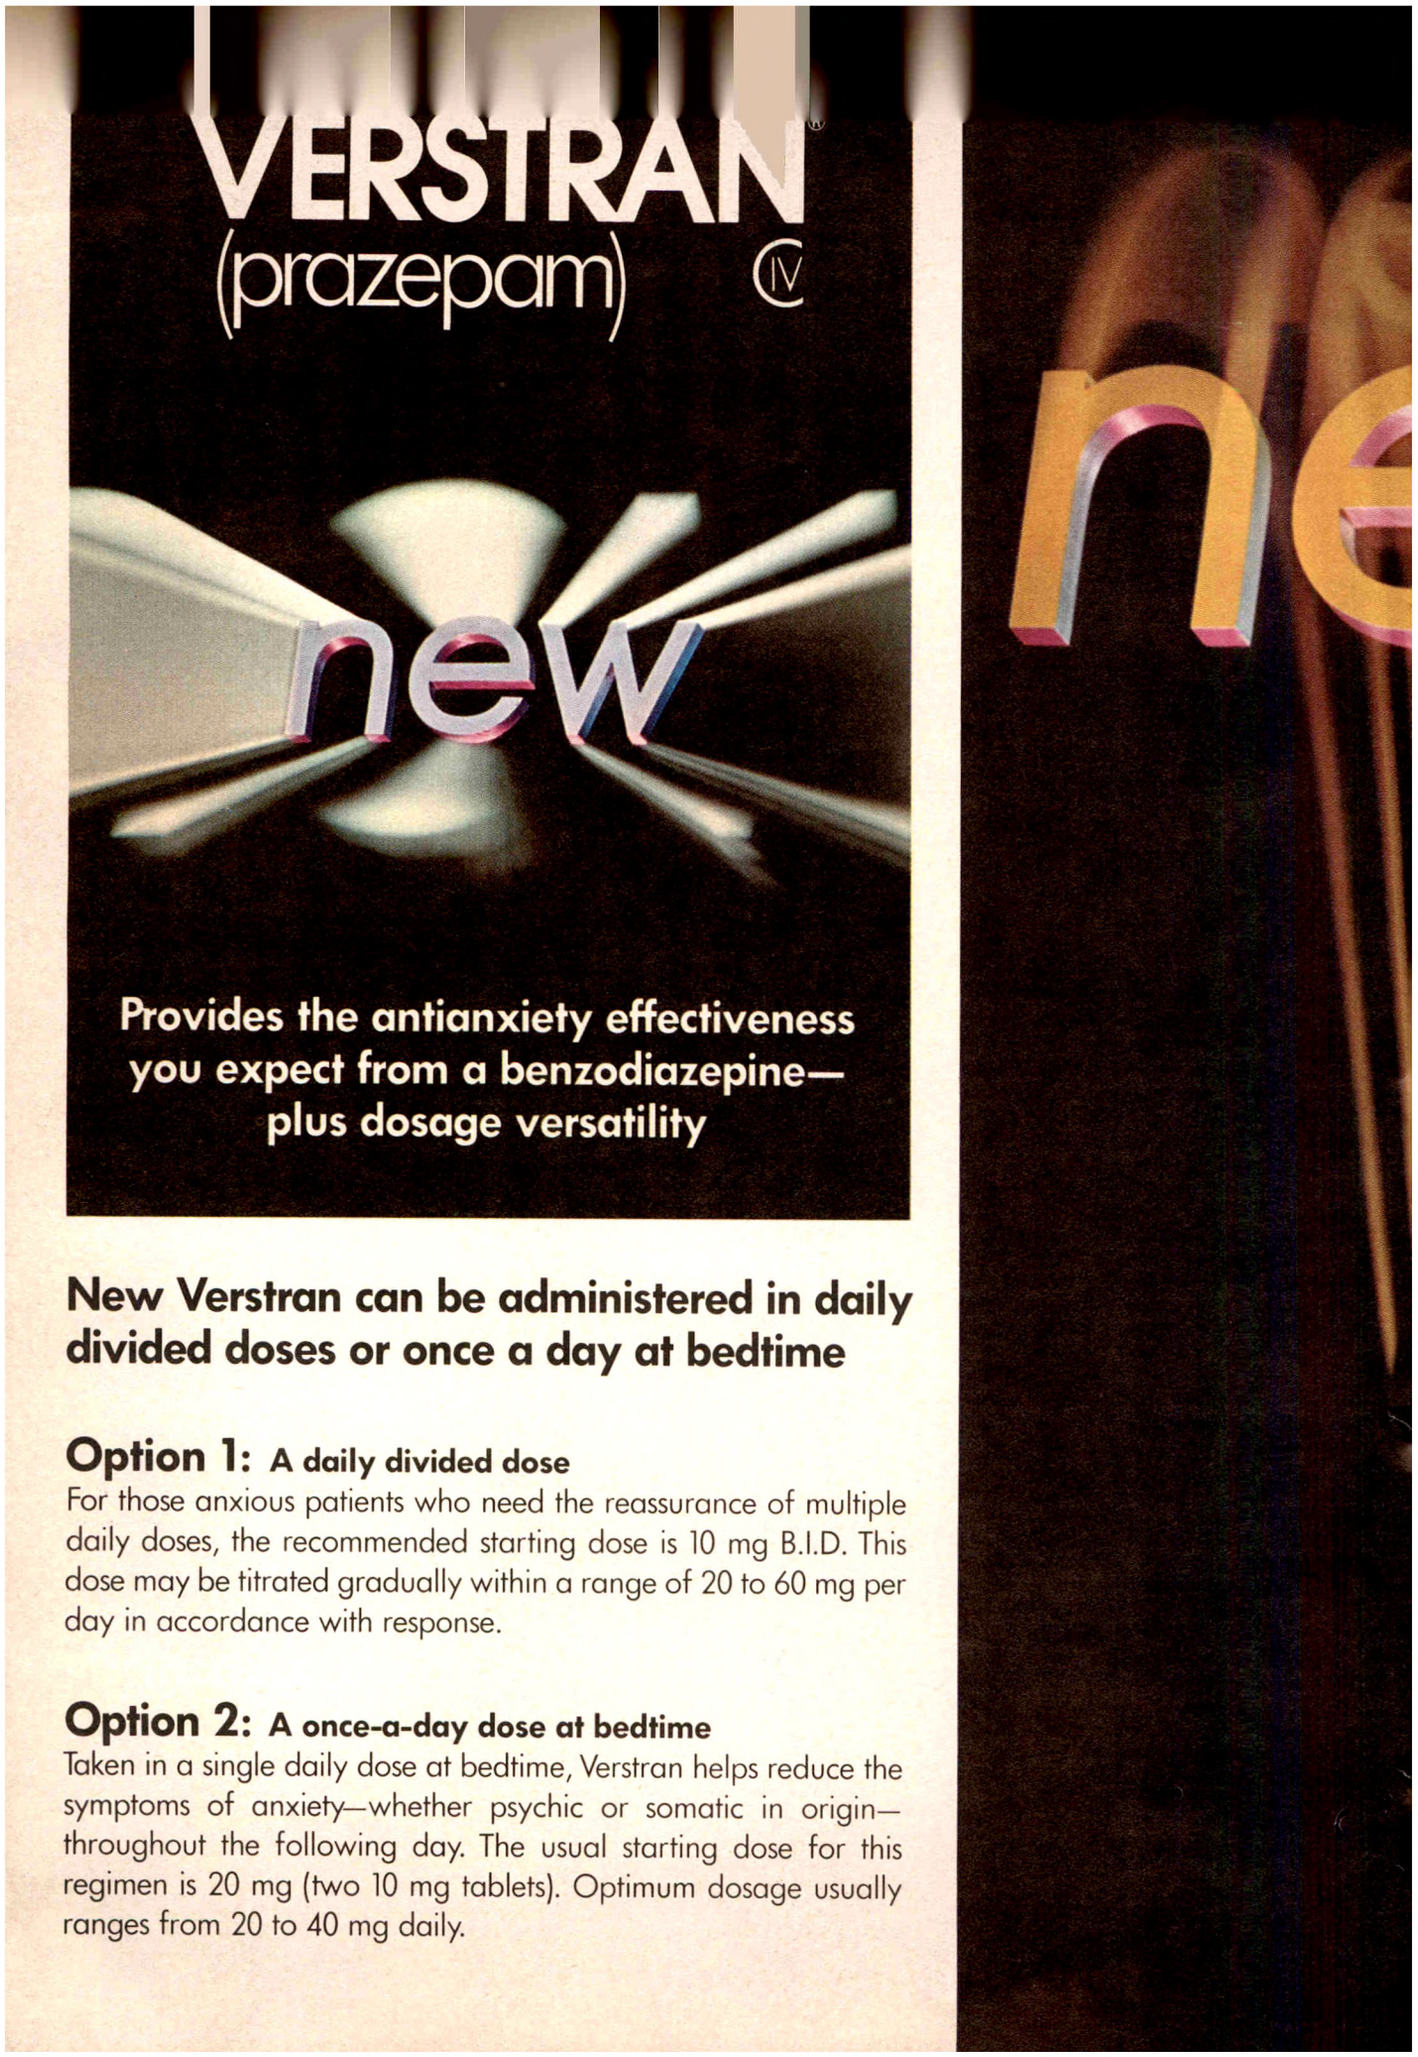
Permits aggressive titration to effective dosage levels,[1,4]
up to 100 mg/day orally (with minimal risk of usual troublesome reactions) to achieve optimal response when patient is inadequately controlled at lower dosage...to help you rapidly control and stabilize new patients, promptly regain control during periods of exacerbation.

Common side effects easily controlled.[1,3-6]
Although extrapyramidal symptoms (EPS) have been reported frequently, they are usually dose-related and readily controlled with dose adjustment or antiparkinson drugs. EPS often diminish spontaneously with continued use of HALDOL haloperidol.

*Not an actual case history, this situation illustrates the action of HALDOL haloperidol as reported in various clinical studies (available on request).

Reduces risk of certain troublesome reactions.[2-5,7]
Transient hypotension occurs rarely and severe orthostatic hypotension has not been reported. Marked sedation is rare, although some instances of drowsiness have been reported. In addition, with chronic use, it is unlikely to cause hepatic damage, serious hematologic reactions, photosensitivity reactions and skin rashes...and has minimal effect on renal function.

Please turn page for information relating to Indications, Contraindications, Warnings, Precautions and Adverse Reactions.

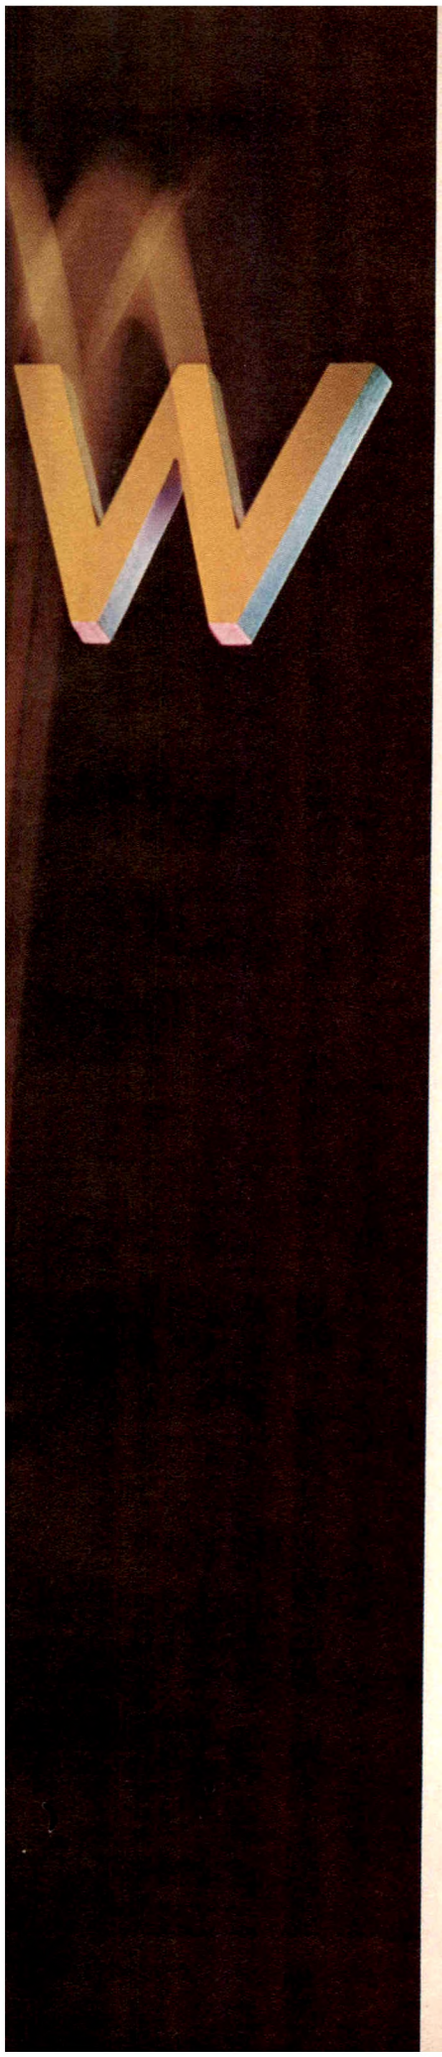


Important: Full directions for use should be read before HALDOL haloperidol is administered or prescribed.

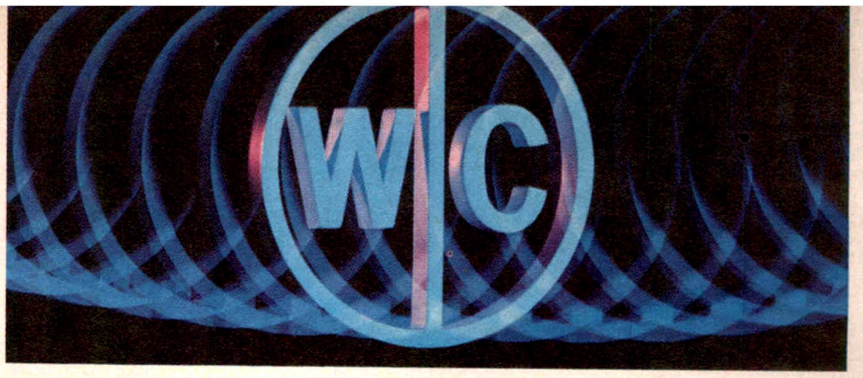
Warner/Chilcott Introduces

VERSTRAN®
(prazepam) C IV

A new addition for the treatment of anxiety

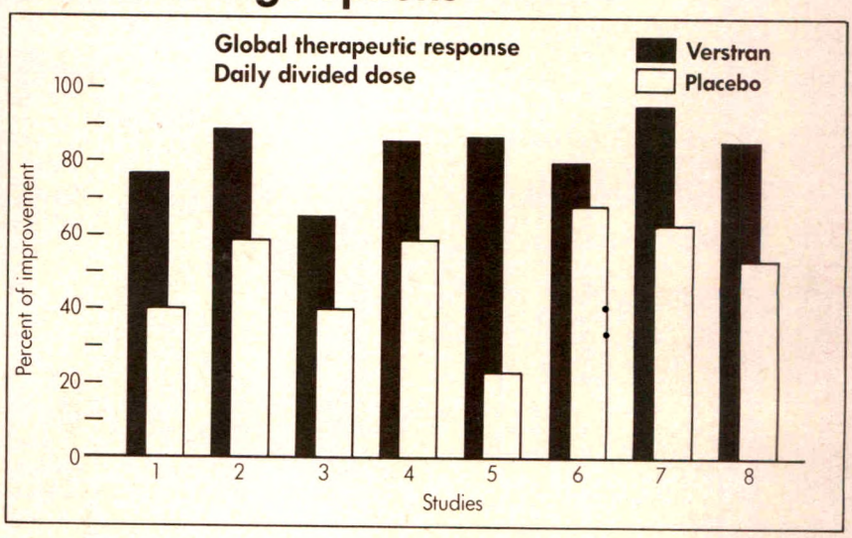


New Verstran can be administered in daily divided doses or once a day at bedtime



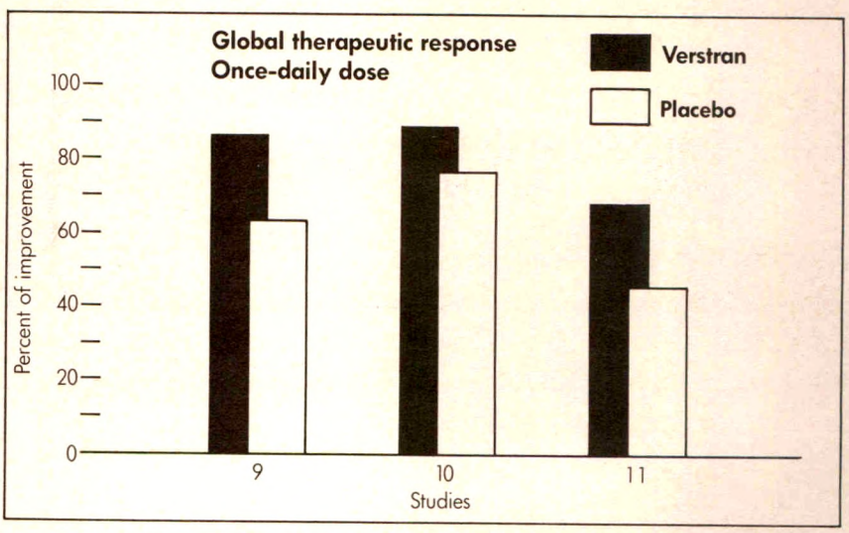
Option 1: A daily divided dose

For those anxious patients who need the reassurance of multiple daily doses, the recommended starting dose is 10 mg B.I.D. This dose may be titrated gradually within a range of 20 to 60 mg per day in accordance with response.



Option 2: A once-a-day dose at bedtime

Taken in a single daily dose at bedtime, Verstran helps reduce the symptoms of anxiety—whether psychic or somatic in origin—throughout the following day. The usual starting dose for this regimen is 20 mg (two 10 mg tablets). Optimum dosage usually ranges from 20 to 40 mg daily.

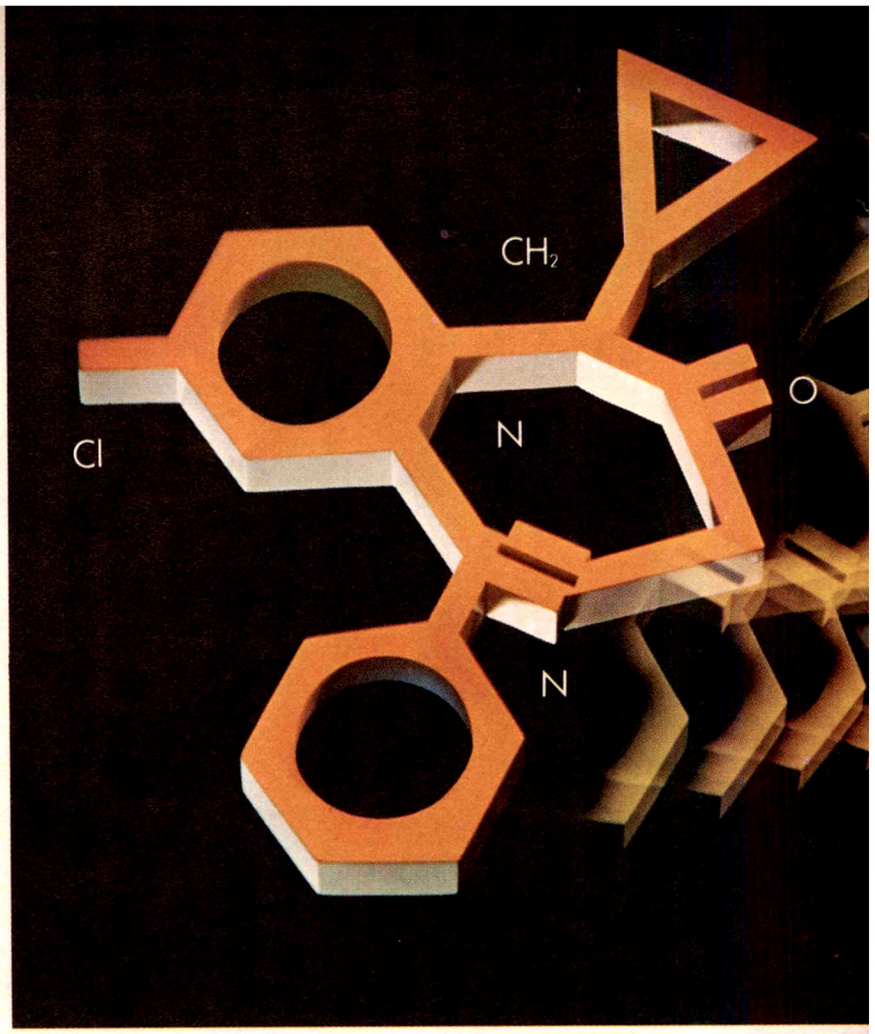


Eleven double-blind studies totaling 560 patients confirm the clinical efficacy of both dosage options*†

Four hundred and four patients suffering nonpsychotic clinical anxiety were given Verstran (228 patients) or placebo (176 patients) in a daily divided dose according to a randomized, double-blind design. Dosage of Verstran was within the recommended limits.

Target symptoms rated include: anxiety, depressive mood, irritability/hostility, tension and insomnia. Global Improvement Ratings were made at week 2, 3, or 4.

One hundred and fifty-six patients suffering nonpsychotic clinical anxiety were given Verstran (70 patients) or placebo (86 patients) once daily at bedtime according to a randomized, double-blind design. Dosage of Verstran was within the recommended limits.



Target symptoms rated include: anxiety, depressive mood, irritability/hostility, tension and insomnia. Global Improvement Ratings were made at week 3 or 4.

*Data on file, Warner/Chilcott Medical Department.

†The number of patients cited represents those evaluated at final observation.

Please see last page of this advertisement for full product information.

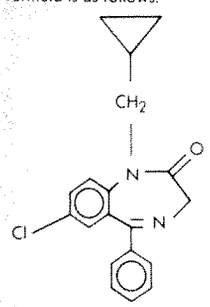
New Verstran provides the simplicity of a single 10 mg tablet strength

Verstran is available in one 10 mg tablet strength only. Titration is simplified, and dosage is easy for the patient to remember. Scored tablets facilitate precise titration.

■ **New Verstran.**
Effective for the symptomatic relief of a wide range of anxiety conditions — whether psychic or somatic in origin.

■ **New Verstran.**
The option of fully effective divided daily or single nighttime dose.

■ **New Verstran.**
The simplicity of a single tablet strength.



■ **New Verstran.**
Side effects are characteristic of benzodiazepine drugs.*

*Please see last page of this advertisement for warnings, precautions and adverse reactions.

Verstran® (prazepam) Ⓒ

Caution: Federal law prohibits dispensing without prescription.

Description: Verstran (prazepam), a benzodiazepine derivative, is identified chemically as 7-chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2H-1,4-benzodiazepin-2-one. The molecular weight is 324.8 and the structural formula is as follows.

Clinical Pharmacology: Studies in normal subjects have shown that Verstran (prazepam) has depressant effects on the central nervous system. Oral administration of single doses as high as 60 mg and divided doses up to 100 mg t.i.d. (300 mg total daily dose) were without toxic effects.

Single oral doses of Verstran in normal subjects produced peak blood levels at 6 hours postadministration, with significant amounts still present after 48 hours. Verstran was slowly absorbed over a prolonged period, rather constant blood levels were maintained, and excretion was prolonged. The mean half-life of prazepam measured in subjects given 10 mg t.i.d. for one week was 63 (± 15 s.d.) hours before and 70 (± 10 s.d.) hours after multiple dosing—a nonsignificant difference. Human metabolism studies showed that prior to elimination from the body, prazepam is metabolized in large part to 3-hydroxyprazepam and oxazepam.

Indications: Verstran (prazepam) is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

Contraindications: Verstran (prazepam) is contraindicated in patients with a known sensitivity to the drug and in those with acute narrow angle glaucoma.

Warnings: Verstran (prazepam) is not recommended in psychotic states and in those psychiatric disorders in which anxiety is not a prominent feature.

Patients taking Verstran should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery, including motor vehicles.

Because Verstran has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, including phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants. The effects of alcohol may also be increased.

Physical and Psychological Dependence: Withdrawal symptoms similar in character to those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepine drugs. These symptoms include convulsions, tremor, abdominal and muscle cramps, vomiting and sweating. Addiction-prone individuals, such as drug addicts and alcoholics, should be under careful surveillance when receiving benzodiazepines because of the predisposition of such patients to habituation and dependence.

Precautions:

Use in Pregnancy and Lactation:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Verstran (prazepam) a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug. In view of their molecular size, Verstran and its metabolites are probably excreted in human milk. Therefore, this drug should not be given to nursing mothers.

In those patients in whom a degree of depression accompanies the anxiety, suicidal tendencies may be present, and protective measures may be required. The least amount of drug that is feasible should be available to the patient at any one time.

Patients taking Verstran for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed. Hepatomegaly and cholestasis were observed in chronic toxicity studies in rats and dogs.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

Pediatric Use: Safety and effectiveness in patients below the age of 18 have not been established.

Adverse Reactions: The side effects most frequently reported during double-blind placebo-controlled trials employing a typical 30 mg divided total daily dose and the percent incidence in the Verstran (prazepam) group were: fatigue (11.6%), dizziness (8.7%), weakness (7.7%), drowsiness (6.8%), lightheadedness (6.8%), and ataxia (5.0%). Less frequently reported were: headache, confusion, tremor, vivid dreams, slurred speech, palpitation, stimulation, dry mouth, diaphoresis, and various gastrointestinal complaints. Other side effects included: pruritus, transient skin rashes, swelling of feet, joint pains, various genitourinary complaints, blurred vision, and syncope. Single nightly dose, controlled trials of variable dosages showed a dose-related incidence of these same side effects. Transient and reversible aberrations of liver function tests have been reported, as have been slight decreases in blood pressure and increases in body weight.

These findings are characteristic of benzodiazepine drugs.

Overdosage: As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

If vomiting has not occurred spontaneously, it should be induced. Immediate gastric lavage is also recommended. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though unlikely, may be controlled with Levophed® (levarterenol bitartrate) or Aramine® (metaraminol bitartrate). Caffeine and Sodium Benzoate Injection, USP, may be used to counteract central nervous system depressant effects.

Dosage and Administration: Verstran (prazepam) is administered orally in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 20 to 60 mg daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a divided daily dose of 10 mg to 15 mg. (See Precautions.)

Prazepam may also be administered as a single dose daily at bedtime. The recommended starting nightly dose is 20 mg. The response of the patient to several days' treatment will permit the physician to adjust the dose upward or, occasionally, downward to maximize antianxiety effect with a minimum of daytime drowsiness. The optimum dosage will usually range from 20 to 40 mg.

Drug Interactions: If Verstran (prazepam) is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monamine oxidase inhibitors or other antidepressants.

If Verstran is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

How Supplied: Verstran (prazepam) 10 mg light blue, scored tablets in bottles of 100 (N 0047-0276-51).

STORE BETWEEN 59°-86° F (15°-30° C).

A new addition for the treatment of anxiety – whether psychic or somatic in origin

Norton

Écrits

A Selection

By JACQUES LACAN

Of the extraordinary constellation of French thinkers since Sartre of the 1940s, Jacques Lacan has taken the longest to achieve general recognition, although he is quite possibly the most influential. As a practicing psychoanalyst and lecturer, he has been widely attended by a whole generation of French intellectuals. This volume, a collection of lectures delivered to gatherings of fellow analysts or students, includes one of Lacan's most radical, far-reaching texts, *The Subversion of the Subject and the Dialectic of Desire in the Freudian Unconscious*; the celebrated *Discours de Rome,* the longest and most sustained exposition of Lacan's thinking; and other papers dealing with various aspects of psychoanalytic theory and practice. $16.75

The Complete Psychological Works of Sigmund Freud

The Standard Edition

Translated and edited by JAMES STRACHEY

The twenty-four volume set of the Standard Edition of the complete psychological works of Sigmund Freud contains the whole of Freud's published writings. The primary aim of the translations was the rendering of Freud's meaning with the greatest possible accuracy but with considerations of style as well. The translations, editorial commentaries, critical apparatus, indexes, and bibliographies make the Standard Edition an unrivalled source of reference for specialist, scholar, and student. $350.00 the set

Available at a 10% professional discount for $315.00 the set, order directly from W.W. Norton. Publisher pays postage.

INTRODUCING
NEW
SINEQUAN® 75 mg
(DOXEPIN HCl) CAPSULE

©1977, Pfizer Inc.

CLEARING OF DEPRESSION
ANTIDEPRESSANT EFFECTIVENESS...
with convenient once-a-day h.s. dosage*
SINEQUAN®
(DOXEPIN HCl)
NEW 75-mg CAPSULE
Also available:
100-mg, 50-mg, 25-mg, 10-mg CAPSULES and
ORAL CONCENTRATE 10 mg/ml, in 120-ml (4-oz) bottles
*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.
See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

IN THE TREATMENT OF CLINICAL DEPRESSION—

NEW SINEQUAN® 75 mg (DOXEPIN HCl) CAPSULE

EXTENDS THE RANGE OF DOSAGE STRENGTHS

PROVIDING ANTIDEPRESSANT EFFECTIVENESS

IN ADDITION TO OTHER, OFTEN BENEFICIAL, PROPERTIES:..

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY GOOD TOLERATION

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have occasionally been reported. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug. Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severity, a starting dose of 25 mg t.i.d. is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.

In more severely ill patients an initial dose of 50 mg t.i.d. may be required with subsequent gradual increase to 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg/day.

As an alternative regimen, the total daily dosage, up to 150 mg, may be given on a once-a-day schedule without loss of effectiveness. This dose may be given at bedtime.

Anti-anxiety effect is apparent before the antidepressant effect. Optimal antidepressant effect may not be evident for two to three weeks.

Overdosage.
A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias and tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus), hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressive supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions to prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbed. The use of activated charcoal has been recommended, as has been continuous gastric lavage with saline for 24 hours or more. An adequate airway should be established in comatose patients and assisted ventilation used if necessary. EKG monitoring may be required for several days, since relapse after apparent recovery has been reported. Arrhythmias should be treated with the appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CNS symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intravenous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine is rapidly metabolized, the dosage should be repeated as required. Convulsions may respond to standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depression. Dialysis and forced diuresis generally are not of value in the management of overdosage due to high tissue and protein binding of SINEQUAN.

Supply. Available as capsules containing doxepin HCl equivalent to 10 mg, 25 mg, 50 mg, 75 mg, and 100 mg doxepin in bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). SINEQUAN 25 mg and 50 mg are also available in bottles of 5000. SINEQUAN Oral Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibrated at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Just prior to administration, SINEQUAN Oral Concentrate should be diluted with approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune or pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number of carbonated beverages. For those patients requiring antidepressant therapy who are on methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mixed together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not with grape juice. Preparation and storage of bulk dilutions is not recommended.

NEW BOOKS

DEMENTIA

by **Charles E. Wells, MD,** Vice Chairman, Dept. of Psychiatry
Vanderbilt University School of Medicine

New edition—2nd / 290 pages / 40 illustrations / $22.00
Contemporary Neurology Series Vol. 15

Dementia is far too complex a subject to be covered completely by any one investigator. In this excellent 2nd edition, Dr. Wells and his 17 eminent contributors report their separate experiences in the diagnosis and treatment of dementia. Thus the book offers a scope of findings probably unmatched in any other single volume on the subject. In addition there are over 1200 references to the literature.

The first chapter is a scholarly definition of dementia—in itself well worth reading. In the following eleven chapters, over 60 possible causes of dementia are extensively reviewed from different perspectives. A variety of diagnostic examinations are detailed, including physical, mental, neurological, roentenographic, EEG and CAT scan, with a number of illuminating illustrations. Beyond that the contributors report on symptomatology, pathogenesis and, when appropriate, specific treatment therapies. This book is a timely and useful compilation of the most advanced knowledge on dementia.

CONTENTS

Dementia: definition and description
Charles E. Wells

Dementia in old age
H. Shan Nang

Diseases presenting as dementia
Gunter R. Haase

Normal pressure hydrocephalus
Robert Katzmann

Viruses and dementia
Raymond P. Roos and Richard T. Johnson

THE MENTAL STATUS EXAMINATION IN NEUROLOGY

by **Richard L. Strub, MD and F. William Black, PhD—Foreword by Norman Geschwind, MD**

New book / 176 pages / 27 illustrations / $7.95 (paper)

Alone among medical texts, this new book deals exclusively and comprehensively with the mental status examination in neurology. It can help the physician determine whether emotional or behavioral change is the result of a specific organic brain disease or psychiatric impairment. It provides a basis for measuring cognitive and emotional deficits as well as residual strengths. In some cases, the information gained may relate damage to certain regions of the brain. Various tests are described in detail—giving suggested questions along with clinically useful interpretations of the probable answers. As a further practical measure, there are two helpful appendices: Standard Psychological Tests and Composite Mental Status Examination. Concise yet thorough, the book is useful for both the busy practitioner and the student.

CONTENTS

Levels of consciousness
Attention
Behavioral observations
Language
Memory
Constructional ability
Higher cognitive functions
Related cortical functions
Summary of examination
Further evaluations
Standard psychological tests
Composite mental status examination

PROGRAM EVALUATION FOR MENTAL HEALTH

METHODS, STRATEGIES, AND PARTICIPANTS
By ROBERT D. COURSEY, GERRY A. SPECTER, STANLEY A. MURRELL, BARBARA HUNT and Contributors

This text focuses on setting up and running evaluation programs for real-life mental health delivery systems. It summarizes the current literature and provides broad conceptualizations about the nature of evaluation activity, practical knowledge of techniques and methods, and strategies for successfully implementing program evaluation.

Particular emphasis is placed on the human component of evaluation and how persons interact with an organization in implementing program evaluation.

SECTION HEADINGS: Methods of Program Evaluation. Strategies for Program Evaluation. Participants in Program Evaluation. Further Resources.

1977, 432 pp., $22.00/£15.60 ISBN: 0-8089-1019-1

LIBRIUM®
(chlordiazepoxide HCl)
5 mg, 10 mg, 25 mg capsules

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

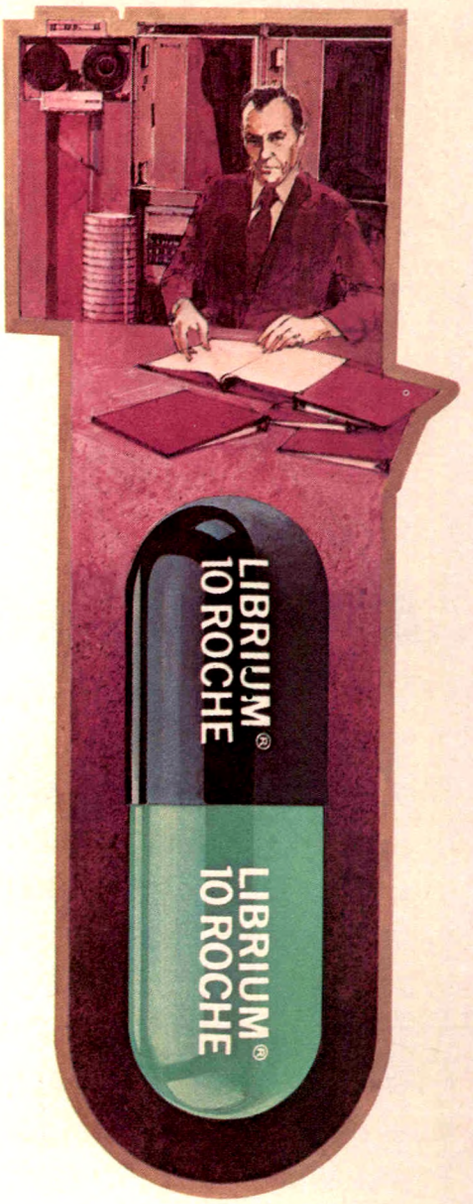
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.



ROCHE
Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

AN OUTSTANDING RECORD OF SAFETY

Anxiety that obstructs the therapeutic relationship often requires adjunctive pharmacotherapy. Selecting an appropriate agent for excessively anxious patients, however, can involve considerations of safety as much as of efficacy.

Because of this, Librium® (chlordiazepoxide HCl) is often an excellent choice. One of the safest antianxiety agents available, Librium is seldom associated with serious side effects (the most common are dose-related and thus largely avoidable). Librium rarely affects the cardiovascular or respiratory systems, rarely interferes with mental acuity. However, as with all CNS-acting drugs, patients should be cautioned against driving and hazardous activities requiring complete mental alertness.

Librium efficacy is a well-documented matter of record. But, equally important, so is its highly favorable benefits-to-risk ratio.

THAT'S WHAT MAKES LIBRIUM® LIBRIUM®

(IV)

chlordiazepoxide HCl/Roche

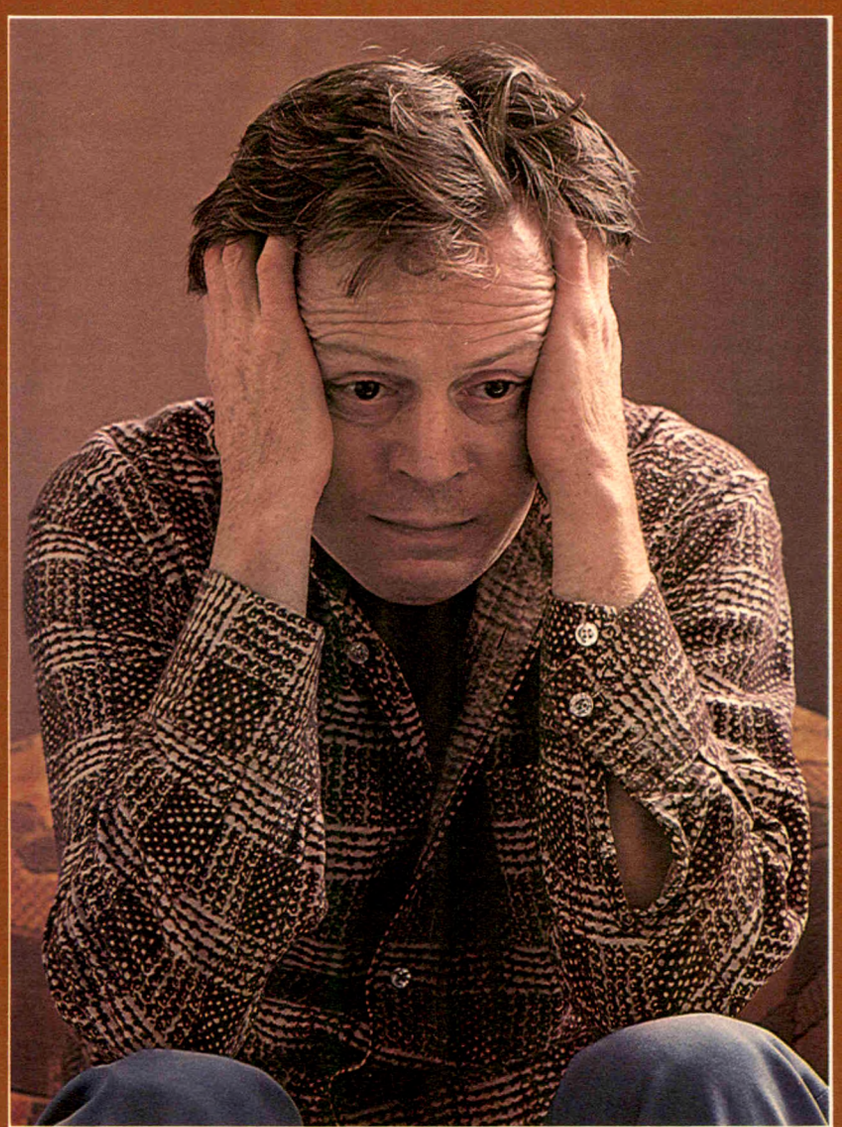
APA PLACEMENT SERVICE
For Employers and Applicants



Those wishing to announce either position openings or availability for employment may register in advance by requesting a listing form by calling Ms. M. J. Merrick (202) 232-7878, ext. 326, or writing to her attention at APA Central Office, 1700 18th Street, N.W., Washington, D.C. 20009. Listing forms should be returned no later than September 26th. On-site listings will also be accepted. However, forms received at the APA prior to the September 26th deadline will have exposure from the very beginning of the Institute. There will be a Placement booth and an interviewing area located in the Institute Registration area (Georgian Room) at the St. Francis Hotel. Listings will be accepted for any mental health related position vacancy/availability.

APPLICANTS—$3 for listing availability
EMPLOYERS—$5 for listing job description

Complete sets of either all applicants or all positions will be available at the close of the Institute at $10 per set.

Dual Problem: marked agitation with depression

...a common problem in psychiatric practice.

MSD
MERCK
SHARP &
DOHME

For a brief summary of prescribing information,
please see last page of this advertisement.

Dual-action TRIAVIL®

containing perphenazine and amitriptyline HCl

Marked agitation accompanying depression is a common problem in psychiatric practice, a problem often requiring dual-action therapy to effectively cope with both components of the disorder. TRIAVIL 4-25 helps treat both. A formulation particularly suited to psychiatric practice when higher doses are required, TRIAVIL 4-25 affords the psychiatrist the opportunity to treat marked agitation—each tablet containing 4 mg of the tranquilizer, perphenazine—while helping to relieve the coexisting depression with 25 mg of the tricyclic antidepressant, amitriptyline HCl.

Helps treat both the marked agitation and the depression

An antidepressant alone may be adequate when the accompanying anxiety is mild, but dual-action TRIAVIL should prove more appropriate when the anxiety or agitation (accompanying depression) is moderate or severe.

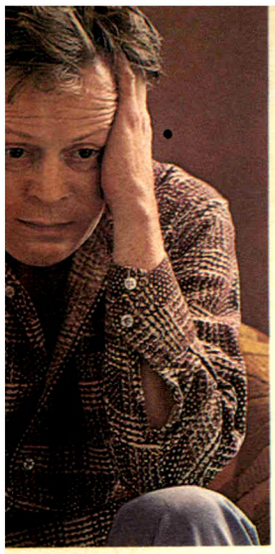
The four formulations of TRIAVIL permit the psychiatrist to treat a relatively broad spectrum of depressed patients who manifest symptoms ranging from moderate anxiety to severe agitation, and allow for individualized dosage adjustment.

The advantages of dual-action TRIAVIL in psychiatric practice.

With TRIAVIL, as anxiety or agitation with depression is relieved, the patient may become more accessible and cooperative. Many symptoms such as insomnia, fatigue, anorexia, and functional G.I. complaints are frequently alleviated; symptomatic relief may enable the patient to function more effectively in his daily activities, and the psychotherapeutic process itself may be aided.

TRIAVIL simplifies therapy; encourages compliance.

A single tablet encourages patients to take medication properly and reduces the risk of dosage confusion and error. Cost of therapy to the patient is usually less than when the components are prescribed individually. To date, clinical evaluations of TRIAVIL have revealed no undesirable reactions peculiar to the combination.



Treatment with TRIAVIL— a balanced view.

TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. It is not recommended in children or during pregnancy. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to other drugs or mask other disorders. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

MSD

MERCK SHARP & DOHME

For a brief summary of prescribing information, please see following page.

for moderate to severe anxiety or agitation and depression

DUAL-ACTION Triavil®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains 2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains 2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains 4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains 4 mg perphenazine and 10 mg amitriptyline HCl.

INITIAL THERAPY FOR MANY PATIENTS
TRIAVIL® 2-25 (or TRIAVIL® 4-25) t.i.d. or q.i.d.

FOR FLEXIBILITY IN ADJUSTING MAINTENANCE THERAPY
TRIAVIL® 2-10 (or TRIAVIL® 4-10)

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.

Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric cris hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism have been reported and can usually be controlled by the concomitant use c effective antiparkinsonian drugs and/or by reduction in dosage, but som times persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy c may occur after drug therapy with phenothiazines and related agents ha been discontinued. The risk appears to be greater in elderly patients on hig dose therapy, especially females. Symptoms are persistent and in som patients appear to be irreversible. The syndrome is characterized by rhyt mical involuntary movements of the tongue, face, mouth, or jaw. Involu tary movements of the extremities sometimes occur. There is no know treatment for tardive dyskinesia; antiparkinsonism agents usually do not all viate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage c the particular drug increased, or another drug substituted, the syndrome ma be masked. Fine vermicular movements of the tongue may be an early sig of the syndrome. The full-blown syndrome may not develop if medication stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythem urticaria, eczema, up to exfoliative dermatitis); other allergic reaction (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions peripheral edema; reversed epinephrine effect; hyperglycemia; endocrin disturbances (lactation, galactorrhea, gynecomastia, disturbances of me strual cycle); altered cerebrospinal fluid proteins; paradoxical excitemen hypertension, hypotension, tachycardia, and ECG abnormalities (quinidin like effect); reactivation of psychotic processes; catatonic-like states; aut nomic reactions, such as dry mouth or salivation, headache, anorex nausea, vomiting, constipation, obstipation, urinary frequency or inco tinence, blurred vision, nasal congestion, and a change in pulse rate; oth adverse reactions reported with various phenothiazine compounds, but n with perphenazine, include grand mal convulsions, cerebral edema, pol phagia, pigmentary retinopathy, photophobia, skin pigmentation, and failu of ejaculation.

The phenothiazine compounds have produced blood dyscrasias (panc topenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinopl lia); and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after lon term administration of some phenothiazines. Although it has not bee reported in patients receiving TRIAVIL, the possibility that it might occu should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia hav also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for th drug, but which have occurred with other pharmacologically similar tricycli antidepressant drugs and must be considered when amitriptyline is admini tered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitatio myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromu cular:* Confusional states; disturbed concentration; disorientation; delusion hallucinations; excitement; anxiety; restlessness; insomnia; nightmare numbness, tingling, and paresthesias of the extremities; peripheral neur pathy; incoordination; ataxia; tremors; seizures; alteration in EEG pattern extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (an diuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred visio disturbance of accommodation; increased intraocular pressure; constipatio paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Ski rash; urticaria; photosensitization; edema of face and tongue. *Hematologic* Bone marrow depression including agranulocytosis; leukopenia; eosinopl lia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric di tress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; paroti swelling; black tongue. Rarely hepatitis (including altered liver function an jaundice). *Endocrine:* Testicular swelling and gynecomastia in the mal breast enlargement and galactorrhea in the female; increased or decrease libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weaknes fatigue; headache; weight gain or loss; increased perspiration; urinar frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abru cessation after prolonged administration may produce nausea, headache, an malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosag should be admitted to a hospital as soon as possible. Treatment is sympt matic and supportive. However, the intravenous administration of 1–3 m of physostigmine salicylate is reported to reverse the symptoms of tricycl antidepressant poisoning. Because physostigmine is rapidly metabolized, th dosage of physostigmine should be repeated as required particularly if li threatening signs such as arrhythmias, convulsions, and deep coma recur persist after the initial dosage of physostigmine. On this basis, in seve overdosage with perphenazine-amitriptyline combinations, symptomat treatment of central anticholinergic effects with physostigmine salicyla should be considered.

Are you prepared

to meet a critical sociomedical problem?

This contemporary new Mosby book helps you prevent and manage drug abuse.

A New Book!

DRUG ABUSE: Clinical and Basic Aspects

Share the insights of 44 outstanding clinicians through this contemporary new presentation of a recurring sociomedical problem. Concise and up-to-date, the book examines profiles of abusers, psychopharmacology of commonly abused drugs, clinical correlations, and potential special clinical problems (including various complications, drug interactions, and overdose). Discussions reflecting the resurgence of alcoholism focus on both psychopharmacologic and clinical factors of alcohol dependency. Other chapters investigate the social, legal, educational, and research aspects of drug abuse. A comprehensive appendix offers you a helpful list of common contaminants of street drugs and a glossary of slang terms.

Edited by S. N. Pradhan, M.D., Ph.D.; associate editor S. N. Dutta, M.D., Ph.D. August, 1977. Approx. 704 pages, 7" x 10", 99 illustrations. About $23.00.

for your staff...

New 2nd Edition!

THE LANGUAGE OF MENTAL HEALTH

This carefully updated new edition includes the most modern terminology used in five areas of the mental health field: mental disorders; human behavior; treatment; administration and law; and related sciences. The authors have retained two appendices that proved popular in the first edition: slang, abbreviations, and colloquial English terms; and historical biographies. They have also added a valuable index of terms defined in the text — arranged according to individual chapter subjects.

By William E. Fann, M.D. and Charles E. Goshen, M.D. February, 1977. 2nd edition, 165 pages plus FM I-X, 7" x 10". Price, $8.50.

THE MYOTRON™ SYSTEM

The first complete pocketsize system to monitor muscle activity.

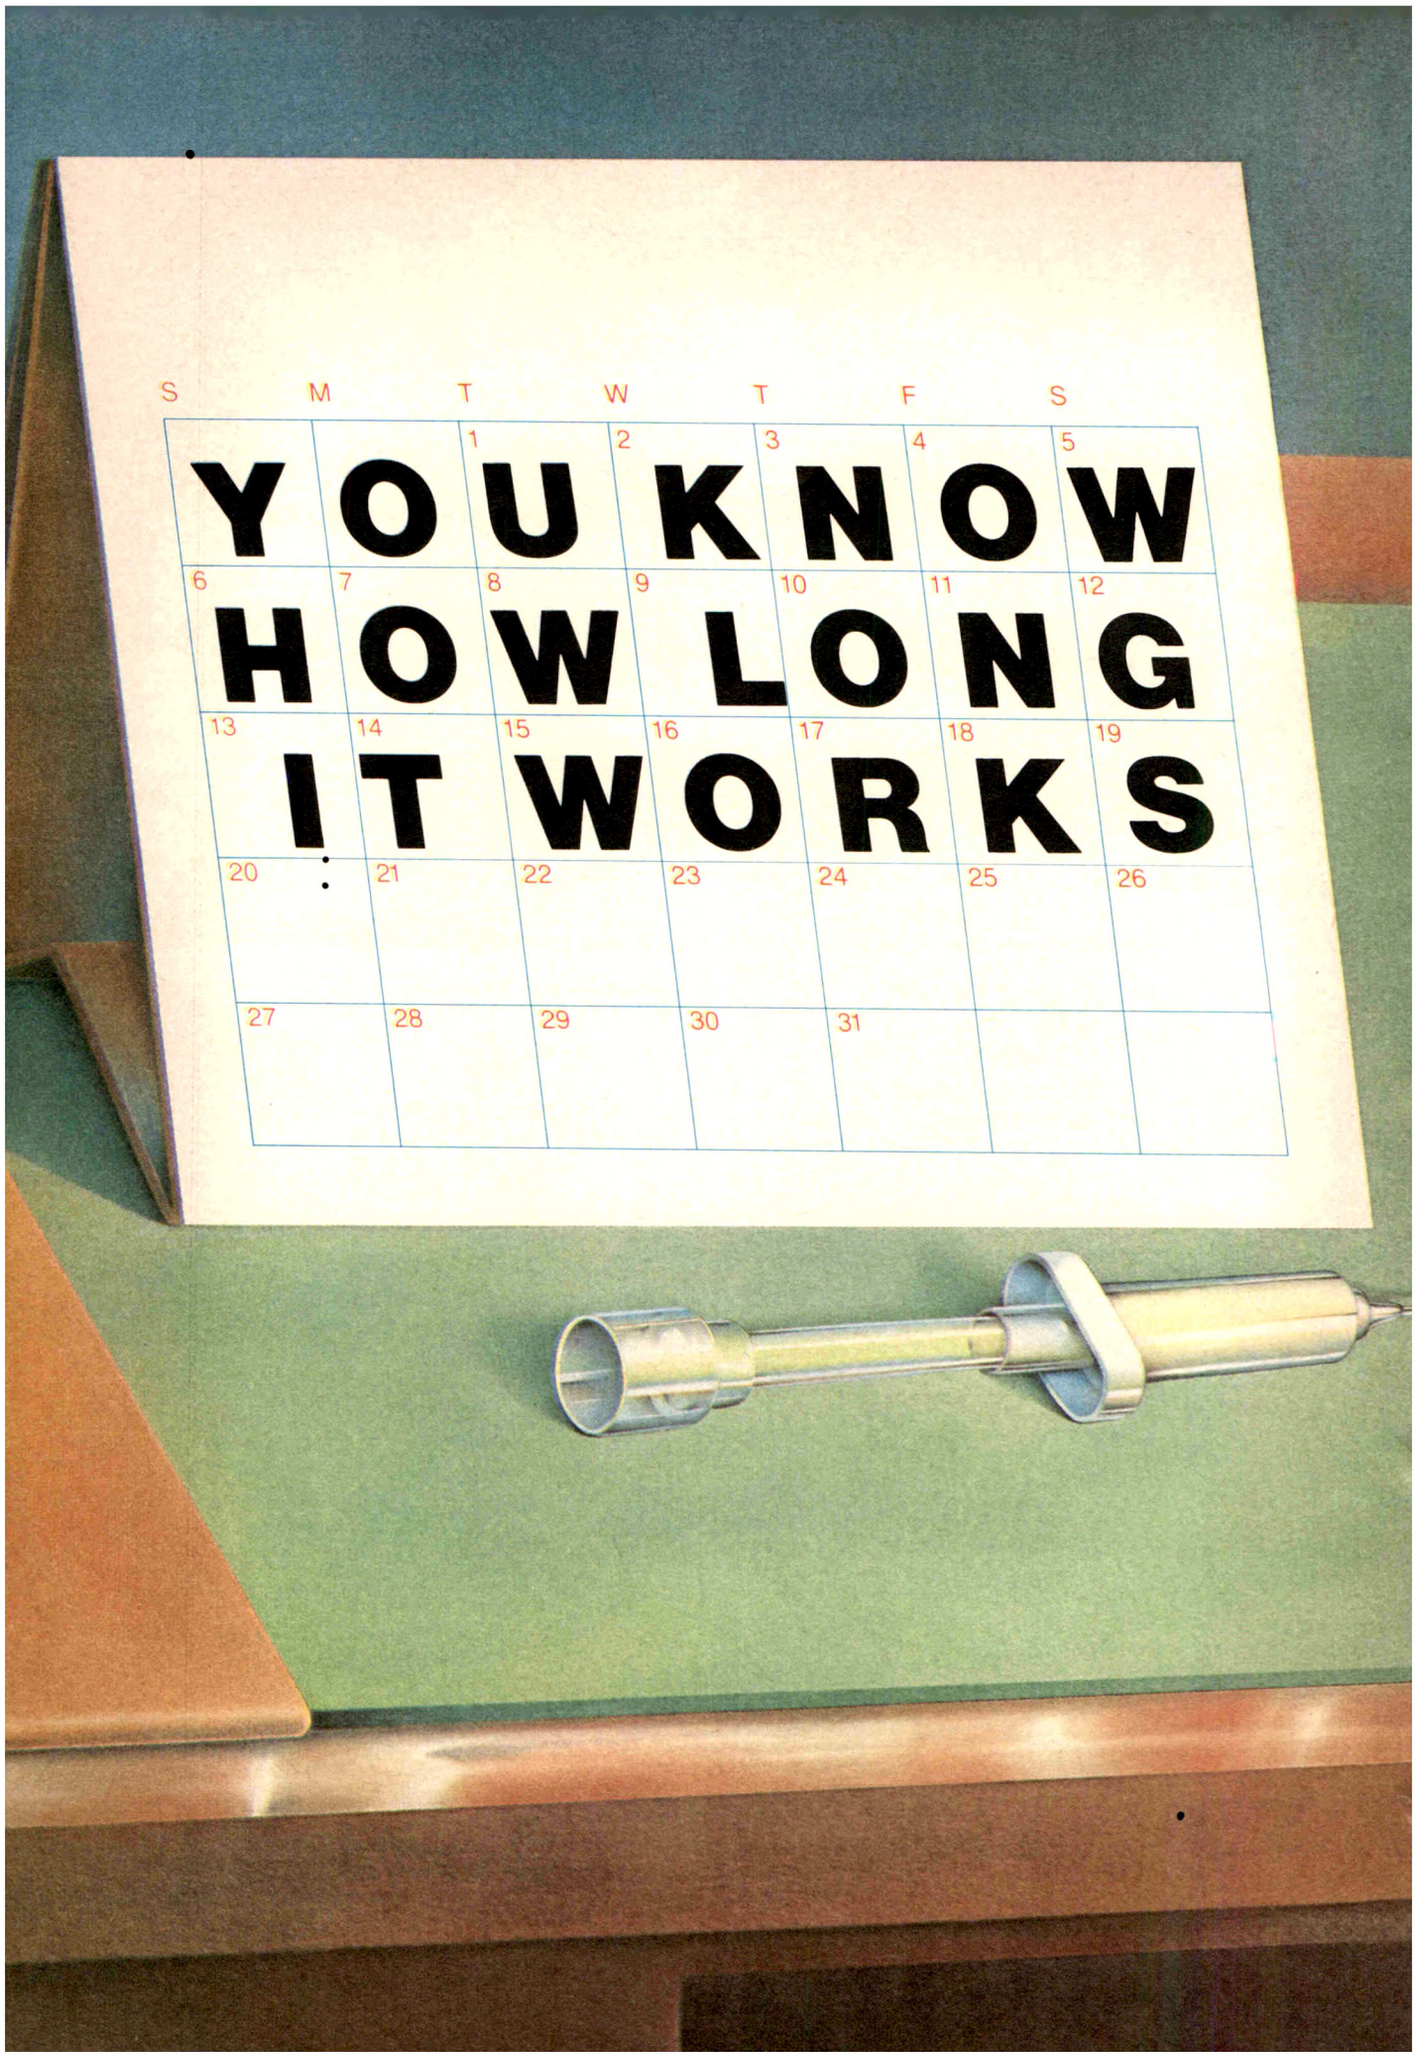
Immediate visual feedback: three light-emitting diodes.

Immediate audio feedback: includes earphone attachment.

Lightweight, portable, compact: can be worn in shirt pocket.

Simple and convenient: ideal for both clinical and home use.

Calibrated response: measures and monitors muscle activity.



Remarkably quiet: heightened sensitivity to muscle relaxation.

High quality, low cost: state-of-the-art electronic circuitry.

HERE'S HOW WELL IT WORKS

Rapidly effective in acute schizophrenia[1]

Average length of hospitalization was 6.1 days (range 1 to 8) for 13 acutely psychotic schizophrenic patients treated with Prolixin Decanoate using the rapid neuroleptization technique. Dosage the first 72 hours averaged 73.2 mg.

Psychotic symptoms diminished rapidly during the first week and continued to abate throughout the 2-month study.

Statistically significant improvement in 13 target symptoms of the Brief Psychiatric Rating Scale, including disorientation, hostility and uncooperativeness, occurred between pretreatment and final evaluation.

Often works where others fail...[2]

Of 52 chronic schizophrenic patients, hospitalized an average 17.5 years, 71% showed clinical improvement after Prolixin Decanoate therapy (25 mg every 7 to 14 days). 32 patients were refractory to prior therapy, including haloperidol combined with chlorpromazine or thioridazine.

General mobilization of the patients was the most significant effect. 7 patients could be discharged from the hospital. In 30 patients refractory to other medication, Prolixin Decanoate tended to inhibit withdrawal symptoms.

...at a fraction of the cost

Prolixin Decanoate therapy at a maintenance dose of 25 mg. every 28 days can cost from 51% to 69% less than the lowest maintenance dosages of several oral medications (see table below).

Comparison of estimated annual hospital costs for oral and injectable therapy, given the following examples:

Drug	Assumed adult dosage*	Form and potency	Cost per unit	Annual cost
Prolixin® Decanoate	12.5-100 mg every 28 days	5 ml vials 25 mg/ml	8.5¢† per mg	$ 13.81 – 110.50
Thorazine®(SKF brand of chlorpromazine)	300-600 mg per day	100 mg tablets bottles of 1000	5.1¢ per tab.**	55.84 – 111.69
Mellaril®(Sandoz brand of thioridazine)	200-800 mg per day	100 mg tablets bottles of 1000	12¢ per tab.**	87.60 – 350.40
Haldol®(McNeil brand of haloperidol)	5-50 mg per day	5 mg tablets bottles of 1000	17.1¢ per tab.**	62.42 – 624.15
Navane®(Roerig brand of thiothixene)	20-60 mg per day	20 mg tablets bottles of 500	24.7¢ per tab.**	90.16 – 270.47

*Dosage level and interval should be determined on an individual basis, in accordance with patient's response to the particular drug as well as the manufacturer's specific recommendations for the use of the product. **Based on prices listed in 1977 Red Book. †Based on Squibb list price of $10.65 per 5 ml vial.

PROLIXIN DECANOATE®
Fluphenazine Decanoate Injection

See following page for brief summary.

PROLIXIN DECANOATE®

Fluphenazine Decanoate Injection

Often works where others fail... at a fraction of the cost

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg. fluphenazine decanoate per ml. in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Physicians should be alert to the possibility that severe adverse reactions may occur which require immediate medical attention. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician experienced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal functions and blood picture should be done. Renal function of patients on long-term therapy should be monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumonias" are possible.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. These include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, and hyperreflexia; most often these are reversible, but they may be persistent. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of antiparkinsonian drugs such as benztropine mesylate or intravenous Caffeine and Sodium Benzoate Injection U.S.P., and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may have to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection U.S.P. is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package insert.

HOW SUPPLIED: 1 ml. Unimatic® single dose preassembled syringes and cartridge-needle units, and 5 ml. vials.

The American Psychiatric Association announces publication of two volumes reporting the Conference on Education of Psychiatrists

held at Lake of the Ozarks, Missouri, June 9-15, 1975. Organized by the A.P.A. in cooperation with the American Academy of Child Psychiatry, the American Association of Chairmen of Departments of Psychiatry, and the American Association of Directors of Psychiatric Residency Training.

1. PSYCHIATRIC EDUCATION: PROLOGUE TO THE 1980's, Library Bound, 544 pages, $15.00.

This is a substantive, highly readable, report of the Conference, written by Anne H. Rosenfeld with an Editorial Board comprising: Ewald W. Busse, M.D., Chairperson of the Conference, Walter E. Barton, M.D., Bernard Holland, M.D., Donna Norris, M.D., Melvin Sabshin, M.D., Jeanne Spurlock, M.D., and Robert L. Robinson, M.A. (Staff Consultant).

The volume contains ten chapters covering the topical structure of the Conference: Goals and Values; Competence, Evaluation, and Quality Control; The Resident; Faculty; Educational Methods: Means in the Service of Ends; The Program Environment; Research; The Economics of Residency Training; Psychiatry in Its Social Context; and Retrospect and Prospect. It also contains nine appendices describing the organization of the Conference and its participants, together with selected model programs and related informational materials of value.

2. THE WORKING PAPERS OF THE 1975 CONFERENCE ON EDUCATION OF PSYCHIATRISTS Paper bound, 432 pages, $12.50.

Sixty two leading psychiatric educators served on seven preparatory commissions, one for each of seven topic areas, and prepared advance working papers as a basis for Conference deliberations. The topics and Commission Chairpersons were: Social Issues and Needs (James N. Sussex, M.D.); Goals and Objectives (Morton F. Reiser, M.D.); The Resident (David R. Hawkins, M.D.); Content, Methodology, Faculty and Environment (Milton Greenblatt, M.D.); Research (Daniel X. Freedman, M.D.); Economics (Herzl Spiro, M.D.); Evaluation and Quality Control (Eric Pfeiffer, M.D.). The Chairpersons, together with the Conference Chairperson, served as the Editorial Board for this volume.

Papers commenting on the reports of the commissions, published here for the first time, were presented at the Conference by Melvin Sabshin, M.D., Eugene B. Brody, M.D., Jeanne Spurlock, M.D., Jack R. Ewalt, M.D., Robert J. Stoller, M.D., James R. Comer, M.D., and Bernard Holland, M.D.

When depression is worse in the morning...

consider the antidepressant with the a.m./h.s. option

Early morning can be the depressed patient's "darkest hour"—the time when he most feels the need for help. Taken at the low point of the classic depressive diurnal rhythm, Norpramin (desipramine hydrochloride) in the a.m. may help patients get started with daily responsibilities, and encourage participation in various forms of psychotherapy.

The a.m. option
Clinical studies show that a single daily administration of Norpramin is as effective and well tolerated as the same quantity given as a divided dosage. This means that Norpramin may be given once daily, morning or bedtime, whichever is most appropriate to the patient's therapeutic need, drug response and activity patterns. A.M. dosage of Norpramin can be especially useful when your depressed patient feels more depressed in the early morning. Morning administration may also help reduce the potential for confusion when other agents are prescribed concomitantly at bedtime.

The h.s. option
For those patients who experience a sedative response to Norpramin, a bedtime dose is most appropriate. Evening administration of Norpramin rarely produces morning hangover.

Minimal daytime drowsiness —permits an active schedule
With Norpramin, problems of daytime drowsiness and morning hangover are largely avoided. Minimal daytime drowsiness can be especially important for patients who must perform daytime activities at home or at work.

Early therapeutic response— builds hope and provides encouragement
While full therapeutic effect may require two to three weeks, onset of action has often been observed in two to five days. Although results have been variable, the weight of scientific reports suggests a faster onset of action with desipramine than with either imipramine or amitriptyline.

Norpramin®
(desipramine hydrochloride tablets NF)
25 mg., 50 mg., 75 mg., 100 mg., 150 mg.

for the patient who must function during the day

Merrell

See following page for prescribing information.

Norpramin®
(desipramine hydrochloride tablets NF)

Brief Summary

Indications: Norpramin (desipramine hydrochloride tablets NF) is indicated for the relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Desipramine hydrochloride should not be given within two weeks of treatment with a monoamine oxidase inhibitor. Contraindications include the acute recovery period following myocardial infarction and hypersensitivity to the drug. Cross sensitivity with other dibenzazepines is a possibility.

Warnings: 1. Extreme caution should be used in patients: (a) with cardiovascular disease. (b) with a history of urinary retention or glaucoma. (c) with thyroid disease or those on thyroid medication. (d) with a history of seizure disorder. 2. This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. 3. *Use in Pregnancy:* Safe use during pregnancy and lactation has not been established. 4. *Use in Children:* Norpramin is not recommended for use in children. 5. This drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. Therefore, the patient should be cautioned accordingly. 6. In patients who may use alcohol excessively, it should be borne in mind that the potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions: This drug should be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with drugs of this class. If possible, dispense in child-resistant containers. It should be kept out of reach of children. Reduce dosage, or alter treatment, if serious adverse effects occur. Norpramin therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates and may cause exacerbation of psychosis in schizophrenic patients. Use cautiously with anticholinergic or sympathomimetic drugs. Response to alcoholic beverages may be exaggerated. In the concurrent administration of ECT and antidepressant drugs one should consider the possibility of increased risk relative to benefits. The sedative effects of Norpramin and benzodiazepines (e.g., chlordiazepoxide or diazepam) are additive. Both the sedative and anticholinergic effects of the major tranquilizers are additive to those of Norpramin. Discontinue as soon as possible prior to elective surgery because of possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients on desipramine hydrochloride. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is neutropenia.

Adverse Reactions: *Cardiovascular:* hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke. *Psychiatric:* confusional states (especially in the elderly), hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis. *Neurological:* numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus. *Anticholinergic:* dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, hypotonic bladder. *Allergic:* skin rash, petechiae, urticaria, itching, photosensitization, edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs. *Hematologic:* bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue. *Endocrine:* gynecomastia, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels. *Other:* jaundice (simulating obstructive), altered liver function; weight gain or loss, perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia. *Withdrawal symptoms:* Though not indicative of addiction, abrupt cessation after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: *Usual adult dose:* 100 mg. to 200 mg. per day. Dosages above 200 mg. per day are not recommended. *Initial therapy:* Should be administered at a low level and increased according to tolerance and response. It may be administered in divided doses or a single daily dose. *Maintenance:* Lower adequate dose once daily to maintain remission. *Adolescent and geriatric patient dose:* 25 mg. to 100 mg. per day, in single or divided doses. Dosages above 100 mg. are not recommended.

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

Presenting
Lidone™
(molindone hydrochloride)
Potent non-phenothiazine
antipsychotic agent new from Abbott

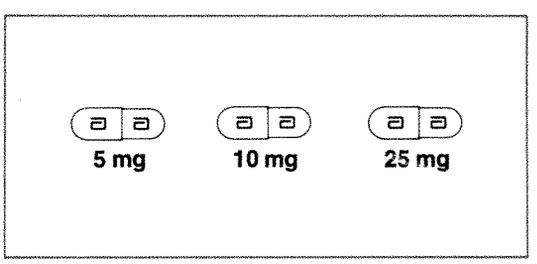
(molindone hydrochloride)

Lidone™ treats the psychosis with little likelihood of causing excessive weight gain or problem sedation

Lidone is molindone hydrochloride, a potent antipsychotic not related to other agents. It is effective against the manifestations of schizophrenia. Yet it is largely free of certain common problems.

Normalizing weight trend seen

Unlike some potent agents, Lidone has not caused excessive weight gain. Though both weight gain and loss have been seen, the shift has typically been toward normal or ideal weight.



Benefits in alertness

Lidone is classed among the "alerting" or less-sedating group of major tranquilizers. If drowsiness does occur during initial therapy, it is usually transient. Patients on continuing Lidone therapy tend to stay alert; hence they can be more responsive to rehabilitation measures.

Improved social outlook

Patients on Lidone have shown good progress in social competence and interest. And side effects such as sexual dysfunction or weight gain, which might disrupt family or interpersonal relationships, have not been reported.

Please contact your Abbott Representative to arrange for a clinical evaluation.

Lidone™ (molindone hydrochloride)

See overleaf for prescribing information.

7083207

Brief summary of prescribing information for

Lidone™ (molindone hydrochloride)

DESCRIPTION — LIDONE (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

LIDONE is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4(5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

ACTIONS — LIDONE (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditional response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, LIDONE antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, LIDONE exerts its effect on the ascending reticular activating system.

Human metabolic studies show LIDONE (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24 to 36 hours. There are 36 recognized metabolites with less than 2 to 3% unmetabolized LIDONE being excreted in urine and feces.

INDICATIONS — LIDONE (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS — LIDONE (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy: Studies in pregnant patients have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats oral dose —
20 mg/kg/day — 2 weeks, no adverse effect
40 mg/kg/day — 2 weeks, no adverse effect

Pregnant Mice oral dose —
20 mg/kg/day — 9 days, slight increase resorptions
40 mg/kg/day — 9 days, slight increase resorptions

Pregnant Rabbits oral dose —
5 mg/kg/day — 12 days, no adverse effect
10 mg/kg/day — 12 days, no adverse effect
20 mg/kg/day — 12 days, no adverse effect

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of LIDONE (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of LIDONE (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

PRECAUTIONS — Some patients receiving LIDONE (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving LIDONE. Caution should be exercised where increased activity may be harmful.

LIDONE does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, convulsive seizures have been reported in a few instances.

LIDONE has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS

CNS Effects — The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological Extrapyramidal Reactions — Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia — Motor restlessness may occur early.

Parkinson Syndrome — Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome — Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System — Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological — There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with LIDONE may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects — Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Lactation associated with LIDONE therapy has not been reported. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with LIDONE.

Cardiovascular — Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological — Lens opacities and pigmentary retinopathy have not been reported where patients have received LIDONE (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with LIDONE.

Skin — Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with LIDONE usage alone.

LIDONE (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when LIDONE is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia — Although rarely reported with LIDONE (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION — Initial and maintenance doses of LIDONE (molindone hydrochloride) should be individualized, and the minimal effective dose should be employed. Elderly and debilitated patients should be started on lower dosage.

DOSAGE SCHEDULE, BASED ON SEVERITY OF SYMPTOMATOLOGY

1. Mild — 5 mg three or four times a day; an increase to 15 mg three or four times a day may be required.
2. Moderate — 10 mg three or four times a day; an increase to 25 mg three or four times a day may be required.
3. Severe — daily dosage as high as 225 mg may be required.

DRUG INTERACTIONS — Potentiation of drugs administered concurrently with LIDONE (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when LIDONE is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE — Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of LIDONE (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of LIDONE (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by LIDONE in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized LIDONE from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of LIDONE is excreted unmetabolized in the urine.) However, poor response of the patient may justify use of these procedures.

While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized LIDONE in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents (i.e., Artane*, Cogentin*, Akineton*).

HOW SUPPLIED — LIDONE (molindone hydrochloride) capsules are supplied in bottles of 100 in the following dosage strengths and colors:

5 mg (NDC 0074-5542-13) blue and cream
10 mg (NDC 0074-5543-13) red and cream
25 mg (NDC 0074-5544-13) brown and cream.

TM — Trademark
*Benadryl — Trademark, Parke Davis and Co.
*Artane — Trademark, Lederle Laboratories
*Cogentin — Trademark, Merck Sharp & Dohme
*Akineton — Trademark, Knoll Pharmaceutical Co.

Announcing Publication . . .

MANUAL OF PSYCHIATRIC PEER REVIEW

by the Peer Review Committee of the American Psychiatric Association, Donald G. Langsley, M.D., Chairperson in cooperation with the Joint Task Force on Diagnostic Criteria for Analyzability of the American Psychoanalytic Association, William Offenkrantz, M.D., Chairperson, and the Peer Review Committee of the American Academy of Child Psychiatry. Larry B. Silver, M.D., Chairperson.

"This Manual provides a set of guidelines for district branches of APA and their peer review committees which should be adapted and modified in terms of local criteria, standards, and practices. The guidelines are not intended to be hard and fast rules. They are screening criteria, and not regulations to control practice. They are so designed that they can be utilized by non-physicians to identify those cases that can profitably be reviewed by psychiatrists serving on peer review committees. This document should be viewed as transitional, subject to revision as experience is gained, and continually updated in response to advances in psychiatric knowledge and changes in patterns of practice. . . . The application of these standards, and refinement through experience must rest with the peer review committees of district branches. . . . It should help them to move ahead in the development of a peer review for American psychiatry."

Robert W. Gibson, M.D.
President

Part I titled PSYCHIATRIC PEER REVIEW contains sections on Basic Relationships and Responsibilities, Appointment of Peer Review Committees, Funding, Operations and Procedures, Medical Care Evaluation Studies, Appeals Processes, Special Problems, Confidentiality, Educational Aspects, Medical Ethics, Advocacy, Interdisciplinary Aspects, with Appendices on Model Screening Format for Inpatient Treatment for Alcoholism, Model Screening Format for Outpatient Treatment, Sample Form for Requesting Extension of Office Treatment, Claims Review Guidelines Suggestions, APA Position Papers on Peer Review, Bibliography.

Part II titled PSYCHOANALYTIC PEER REVIEW has sections on Steps in Peer Review for Psychoanalysis, Guidelines for Model Criteria Sets, Pilot Application of Guidelines for Model Criteria Sets, Sample Peer Review Form, Sample data from Pilot Applications of Guidelines, and Glossary of Terms Used.

Part III titled PEER REVIEW AND CHILD PSYCHIATRY contains sections of Special Considerations, Legal Rights of Children, Issue of Confidentiality, Conclusions, References, and Appendices on Model Screen Criteria Format for Intermediate Care, for Acute Care in a Short Stay Facilities, and for Partial Hospitalization, Outpatient Diagnostic Evaluation Procedures, and Outpatient Treatment for Children and Adolescents.

Published by the American Psychiatric Association, Washington, D.C., September 1976. 114 pages. Spiral binding. Single copies, $6.00. For orders of 10 or more, $5.00 per copy.

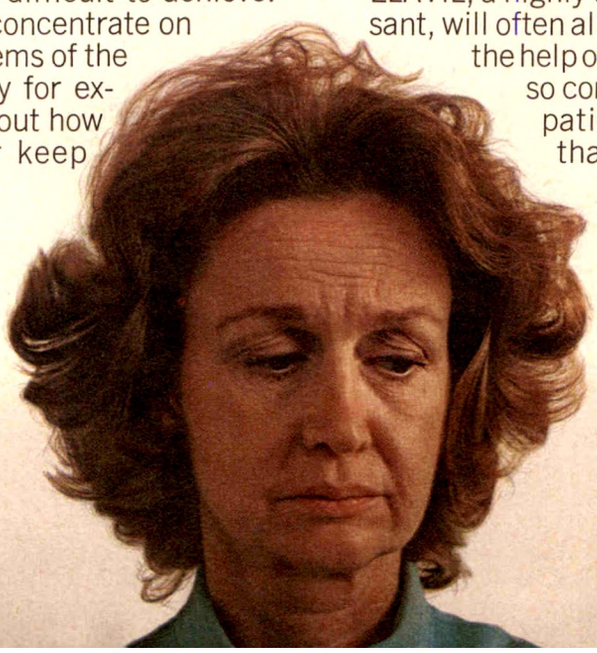
in clinically significant depression...



penetrating the symptom barrier to productive psychotherapy

symptoms often interfere with therapy

In clinically significant depression, the patient often becomes barricaded behind his own symptoms during psychotherapy. Because these symptoms can be so sharply defined and somatic in expression, he may reject the fact that they are psychic in origin. Sleep disturbance, gastrointestinal complaints, anorexia, chronic fatigue, and other psychosomatic symptoms may so preoccupy—or overwhelm—the depressed patient that truly productive therapeutic sessions are difficult to achieve. Instead of being able to concentrate on the core emotional problems of the depression itself, he may for example go on at length about how broken his sleep is or keep reiterating (while the therapeutic hour slips by) how physically miserable he feels.

ELAVIL®
(AMITRIPTYLINE HCl, MSD)
to help penetrate the symptom barrier in depression requiring medication

ELAVIL, a highly effective tricyclic antidepressant, will often alleviate these symptoms. With the help of ELAVIL, sleep disturbance—so common in clinically depressed patients and often the symptom that distresses them most—as

well as other "barrier symptoms" may be lessened to the point where they no longer come between you and the patient.

psychotherapy takes direction

As these preoccupying complaints are lifted, psychotherapy sessions can become more productive. Patients are enabled to respond more fruitfully during therapeutic hours and to resume or pursue more efficiently the necessary activities in their personal lives.

meeting therapeutic goals

And as the antidepressant activity of ELAVIL (Amitriptyline HCl, MSD) takes hold, it helps relieve the depressive condition itself. Sometimes only a minimum of actual psychotherapy is required. The patient may experience a more rapid recovery—while you conserve valuable time.

Prescribe ELAVIL then, to help lighten the patient's burden in depression—and yours in its management.

ELAVIL should not be used during the acute recovery phase following myocardial infarction; in patients hypersensitive to it; in those who have received an MAOI within two weeks; or in children under 12. Patients with cardiovascular disorders should be watched closely. Safe use during pregnancy and lactation has not been established. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Hospitalize as soon as possible any patient suspected of having taken an overdose.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
INJECTION: 10 mg per ml

addendum

To further simplify once-daily therapy for many depressed patients

Tablets

ELAVIL®

(AMITRIPTYLINE HCl | MSD)

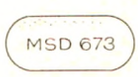
ONE TABLET, ONCE DAILY

—an appropriate way to prescribe for many depressed adult outpatients. Because of its simplicity, this regimen helps improve patient compliance. Of course, ELAVIL may also be prescribed in divided daily doses.

ONCE-DAILY DOSAGE SCHEDULE FOR ADULT OUTPATIENTS:

A single 75-mg tablet
Usual starting dosage

A single 100-mg tablet
Maximum starting dosage



A single 50-mg tablet
Minimum starting dosage

Dosage may be increased by 25 or 50 mg as necessary until a total of 150 mg per day is reached.

A single 150-mg tablet
Maximum daily dosage

ELAVIL MAY ALSO BE PRESCRIBED IN DIVIDED DAILY DOSES

The 25-mg tablet

This strength may prove useful when therapy is initiated with divided daily doses in adult outpatients. Starting dosage is usually 75 mg daily. If necessary, this dosage may be increased gradually to a total of 150 mg a day. Increases are made preferably in the late afternoon or bedtime dose.

The 10-mg tablet

This strength may prove useful for patients who require lower doses, e.g., adolescent and elderly patients. For these patients who can not tolerate higher doses, 10 mg three times a day with 20 mg at bedtime may be satisfactory.

A sedative effect may be apparent before the antidepressant effect of ELAVIL is noted. An adequate therapeutic effect may take as long as 30 days to develop.

NOTE: The usual maintenance dosage of ELAVIL is 50 to 100 mg per day which may be given in a single dose preferably at bedtime. In some patients 40 mg per day is sufficient. This drug is not recommended for patients under 12 years of age.

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.
When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

ELAVIL®
(AMITRIPTYLINE HCl, MSD)

MSD
MERCK SHARP & DOHME

OFTEN ACCOMPANIES DEPRESSION

In 14 double-blind studies, of 339 patients with depressive neurosis who received Mellaril (thioridazine) over half had measurable relief within one week. Relief of the anxiety component was seen in 54.6% (185 of 339 patients) within the first week; relief of the depressed-mood component was seen in 53.4% (181 of 339 patients); relief of insomnia secondary to depression was seen within the first week in 50.2%, or 132 of the 263 patients with this symptom; and overall improvement was seen in 51.3% (174 of 339 patients) in the first week and in 86.4% (293 of 339 patients) by the end of the fourth week.

The most common side effects are drowsiness and dry mouth. Mellaril (thioridazine) is not habituating and usually does not cause euphoria or undue sedation. (The physician should, however, caution patients against participating in activities which require complete mental alertness, e.g., driving.)

in short-term therapy of moderate to marked depression
with variable degrees of anxiety in patients with depressive neurosis

MELLARIL® (THIORIDAZINE)

TABLETS: 10 mg, 15 mg, 25 mg, and 50 mg thioridazine HCl, USP

For Brief Summary, please see following page.

SANDOZ
SAN 6-646R

in short-term therapy of moderate to marked depression with variable degrees of anxiety in patients with depressive neurosis

MELLARIL®
(THIORIDAZINE)

RESULTS OFTEN SEEN IN A WEEK

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient. In adults with depressive neurosis the usual starting dosage is 25 mg t.i.d. and the dosage ranges from 10 mg b.i.d. to q.i.d. in milder cases to 50 mg t.i.d. or q.i.d. for more severely disturbed patients; the total daily dose ranges from 20 mg to a maximum of 200 mg.

THE AMERICAN JOURNAL OF PSYCHIATRY

Accountability, Public Policy, and Psychiatry

BY ANNE R. SOMERS

The author identifies the direction of changes in health policy in the United States that need to be taken into account by the health professions in their dealings with government. She discusses three areas in which these changes will call for adjustment on the part of the medical profession and major health care institutions and defines the special challenge to psychiatry implicit in the changes. She concludes that the public's need for attention to the psychosocial aspects of health and the renewed interest in prevention present psychiatry with an opportunity to provide leadership in health care delivery.

THE CONCEPT of "public accountability" involves two essential ingredients: 1) genuine participation by professions and institutions in the private sector in the formulation of public goals and 2) a commitment to work toward such goals in a fiduciary or stewardship role, including an ongoing "accounting" to the public for this stewardship. Stated a little differently, the concept presupposes not only the continued existence of the private sector but also a large degree of professional and institutional independence. The opposite side of the coin is that the professions and the institutions may expect to retain their private status only as long as they act as if they were public.

This may seem a meaningless distinction but, in fact, it is important. If we, in America, can achieve a combination of public goal-setting and private-sector implementation, avoiding the evils of overcentralization and overbureaucratization implicit in too much direct government control, we will have made a major contribution to the development of democratic self-government.

Public accountability might be likened to the "categorical imperative" propounded some 200 years ago by Immanuel Kant. At a time when philosophers were hotly debating the existence of God and the relevance of competing ethical principles, Kant concluded that, while His existence could not be proved, it behooved the individual to conduct himself "als ob" or "as if" the universe were ordered in accordance with universally binding moral law.

The concept is particularly relevant and useful in the health field. Considerations of professional responsibility and public trust are deeply embedded in the health professions and in hospital history. They are implicit in the Hippocratic oath and explicit in state licensing laws. It is obvious that the government cannot take over and run the nation's health care system or even a single hospital without the cooperation of the majority of professionals involved. It is equally obvious, in this day of multibillion-dollar health care costs, that private professions and institutions cannot function effectively without government participation and without implied acceptance of publicly defined goals.

I congratulate Dr. Gibson and the other officers of the American Psychiatric Association for their timely choice of theme for this meeting, "Professional Responsibility and Public Trust" (1). Public accountability is an essential aspect of this theme. After reading Dr. Marmor's 1976 Presidential Address (2), it is impossible not to conclude that the leadership of APA understood and accepted the implications of public accountability long before it became such a popular phrase. The challenge remains, however, to translate these lofty presidential ideals into the everyday thinking and practice of the 22,000 physicians who make up APA's membership. This, of course, is the real test of leadership, as well as of the viability of the concept.

Of the two components in my definition of public accountability, the second—procedures for accounting to the public with respect to professional performance or stewardship—has evoked the most discussion.

Revised version of the William C. Menninger Memorial Convocation Lecture, presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977.

Ms. Somers is Professor, Department of Community Medicine and Department of Family Medicine, College of Medicine and Dentistry of New Jersey-Rutgers Medical School, Piscataway, N.J. 08854.

Professional Standards Review Organizations (PSROs) and other forms of quality control, utilization review, certification and recertification, and continuing education—the crucial implementing procedures—deserve all the attention they are receiving, and more. However, I intend to focus on the other component—public-private cooperation in the formulation of broad social goals, goals to which the private organizations will consider themselves committed and for whose implementation they will accept responsibility. I have chosen this focus because I believe that a great deal of the present antagonism between public and private sectors derives from failure to agree on mutually acceptable goals or even to appreciate the necessity of such goals.

Part of the problem is the inconsistency—sometimes to the point of direct contradiction—of the policies that the bureaucrats must implement. This inconsistency results from two major considerations: 1) the structure of our pluralistic form of government, which strongly favors special group interests rather than monolithic or holistic policies, and 2) the difficulty of eliminating old agencies even when their functions have become obsolete. Old bureaus never seem to die; sometimes they don't even fade away!

These are serious defects in our form of government and were probably among the conditions that led Winston Churchill to say, "Democracy is the worst possible form of government—except all others!" However, I doubt that any of us is prepared to exchange our often ambiguous pluralism for the clear-cut mandates of totalitarian government. We have learned to live with considerable ambiguity, and I suspect we will continue to do so. On the other hand, we could reduce the confusion considerably if we could learn to think about public policy as evolving in a dynamic, constantly changing context. Policies must and will change in response to changing scientific, technologic, socioeconomic, and demographic conditions. The more rapid the underlying shifts, particularly the scientific, which trigger most of the others, the more rapid changes in public policy have to be.

In this paper I shall try to do three things: 1) identify the direction of change in U.S. health policy today—providing a kind of forecast of the prevailing socioeconomic and political winds that the health professions would be advised to take into account in their dealings with government; 2) discuss briefly three specific areas in which these prevailing winds will probably call for considerable adjustment on the part of the medical profession and major health care institutions; and 3) provide some conclusions regarding the special challenge to psychiatry implicit in these trends.

THE DIRECTION OF CHANGE

There is no question but that the United States is in the midst of a new sociopolitical revolution. No one knows exactly how to define it, much less where it will take us. Some speak nostalgically of "the end of the American dream," meaning, usually, an end to economic growth, an ever-rising material standard of living, and maximum personal freedom—to do one's own "thing." Others, emphasizing the moral and political bankruptcy associated with Viet Nam and Watergate, see our present difficulties as an opportunity for a spiritual renaissance, an emergence from a long period of overemphasis on materialism.

President Carter's energy policy typifies the new mood. Although there is no abrupt break with the past, the differences in emphasis are considerable. Gone is the sense of limitless resources, replaced by a sober appraisal of limited resources. Gone is a one-dimensional approach to causation and cure, replaced by a complex multifactorial analysis and equally complex prescriptions for management. Gone is the assumption that the situation can be managed either by private enterprise alone or by government alone, replaced by a call for a difficult but essential working relationship. The two knee-jerk reactions that one might have heard in the past—"Nationalize the oil fields!" or "Get the government out of business altogether!"—are both conspicuously missing. Gone also is the idea that the individual consumer has no responsibility, replaced by a call for considerable responsibility and even some sacrifice.

It remains to be seen whether the President will be able to sell this policy to Congress and the American people, many of whom still prefer to attribute our problems to foreign plots, demons, and assorted personal villains, but at least the first reaction suggests a more mature, sensible public opinion than some pessimists had anticipated.

I mention energy because there are some important analogies to the situation in health. For a quarter-century after World War II the health field was characterized by the euphoric view that resources were limitless; all we had to do was design financing programs to remove barriers to access and use public money to subsidize the expansion of facilities and personnel. We now know that a national health policy keyed almost exclusively to greater access will result in vastly increased expenditures but not necessarily in proportionately better health. For a quarter-century health policy has been dominated by the one-dimensional view of illness and disability as resulting primarily from inadequate medical care, especially somatic care. We now know that good medical care is only one of the many factors affecting health; others include the individual's biological makeup and environmental and behavioral components. For a quarter-century people have been led to believe that some external body—the government, the hospital, the HMO, the neighborhood health center, the AMA—was responsible for their personal health, or the lack of it. We now know that, although responsibility has to be shared by those who can give or withhold information, care, and assistance when needed, the ultimate responsibility rests with the individual.

I do not know whether the new Administration will succeed or even try to translate our better understanding of health care into a new health policy more attuned to the realities of the late 1970s. A widespread groping for new directions has been evident for some time (3–6), even in the U.S. Department of Health, Education, and Welfare (7). Some of President Carter's campaign speeches indicated movement in this direction. Certainly the mental health field has reason to welcome establishment of the new President's Commission on Mental Health, with its broad mandate and composition.

The most carefully articulated official statement to this effect has come from the Canadian Government. The Lalonde report, *A New Perspective on the Health of Canadians* (8), has provided students of health care in the United States, as well as in Canada, with a challenging formulation of national health policy based on a new concept of the "Health Field."

Herman Somers and I have published a proposal (9, 10) that we hope will contribute to the formulation of a new American policy. We take our cue from the European epidemiologist, Dr. Rene Sand, who said, "Health cannot simply be given to the people; it demands their participation." Then we go on to say,

> Any new design that will prove effective must be based on two broad assumptions:
>
> 1. Responsibility for personal health rests primarily with the individual; not with government, not with physicians or hospitals, not with any third-party financing program. Meaningful national health policies must be directed to increasing, rather than eroding, the individual's sense of responsibility for his own health and his ability to understand and cope with health problems.
>
> 2. If the individual's responsibility is to be effectively discharged, it must be supported by social policies designed to provide him with essential environmental protection, health information, and access to health care when needed.
>
> In short, a policy of "individual responsibility" and a policy of "social responsibility" are complementary, not antithetical. Neither can be fully effective without the other. The term that seems best to suggest an approach that encompasses both assumptions is "health promotion." The overriding goal of such a national health policy may be stated as: The creation and maintenance of conditions under which individual Americans are most able and most likely to optimize their own health potential.

We then go on to classify the major conditions affecting individual and national health under several broad headings; i.e., genetic endowment, the environment, behavioral factors, access to good health services, and the scientific state of the art in all categories.

This does not reflect official U.S. health policy at the present time. Even the Lalonde report, which, unlike ours, is official, is not universally accepted, much less implemented, throughout Canada. However, the leadership of the health professions may wish to consider these new formulations and their implications for emerging public and professional policies. These implications may become clearer if we consider three specific issues: comprehensive care, cost controls, and prevention.

THREE AREAS OF CHANGE

Comprehensive Care

In theory, there is widespread agreement that Americans should have access to "comprehensive care," i.e., preventive, diagnostic, therapeutic, rehabilitative, and long-term services, as needed and with equal attention to physical and mental illness. The spectrum is sometimes defined more simply as primary, secondary, and tertiary care. Long-term care is sometimes subsumed under primary care, sometimes added as a fourth category.

The practice, however, is quite different from the theory. The realities of health care financing—both public and private—which reflect priorities of the past, prior to the emergence of chronic illness as the major cause of morbidity, strongly bias availability in the direction of the more specialized and expensive modalities associated with tertiary care. For example, although about 80% of the population under the age of 65 had some hospital and surgical coverage under private health insurance in 1974, only 62% had any coverage for physicians' office visits, and only 35% for nursing home care (11). Only 11% of the "working poor" had any coverage for out-of-hospital services (12, p. 21). A similar pattern can be seen in Medicare expenditures. In fiscal 1975, for example, this pattern-setting program paid for 72% of the hospital expenses of the elderly, 54% of the physicians' fees (mostly for in-hospital services), 3% of the costs for skilled nursing care, and 4% of all other costs (13).

Such financing and other government subsidies encourage the provider tendencies subsumed under the familiar maxims, "the technological imperative" and "the edifice complex." Today, most physicians are not in primary care. They are specialists or superspecialists, generally attuned to tertiary care. Most, sometimes all, of their clinical training takes place in hospitals. Prestige in the profession leans heavily to the accomplished diagnostician, who is greatly dependent on the imposing armamentarium of the tertiary institution. The "battery of tests" syndrome has recently found a new rationalization in "defensive medicine."

Hospitals are driven by similar stimuli. Each wants to be bigger, to offer a broader range of services, to be the "best." Prestige comes from attracting prominent specialists to the staff, and this requires more and better technological equipment and plenty of beds, all of which leads to expanded capitalization, higher operating costs, and pressure to "fill the beds." If money to pay for all this appears virtually assured—over 91% of all hospital costs were paid by third parties in fiscal 1977 (14, p. 10)—there is not much to restrain these "natural" tendencies.

Such developments led Dr. Alexander Leaf, physician-in-chief at Massachusetts General Hospital, to observe recently, "We are doing too much for too few, at too great a cost, and with too little benefit." In light of their training, it is often difficult to persuade physicians that postponement of death is not the sole purpose of health care. Matters such as pain, patient preference, medical expense, and social costs are competing considerations and, in some terminal contexts, may outweigh the prolongation of life. At the extreme, we have the appalling extent to which people in hopelessly comatose states are kept indefinitely alive by a panoply of mechanical and chemical interventions, dramatized in the celebrated case of Karen Quinlan (15).

While Medicare, Medicaid, and private health insurance pump tens of billions of dollars into the tertiary institutions, the public demand for adequate primary care and long-term care for the elderly and the chronically ill, including the mentally ill and retarded, remains unanswered. Some progress is being made in these areas. Congress (Public Law 93-641), DHEW (7, pp. 50–51), and the Robert Wood Johnson Foundation (16) have all declared that primary care, especially for underserved areas, is a top national health priority. Medical students are being bribed and bludgeoned to go into primary care for at least a year or two. Medical schools are exhorted to include more primary care in their curricula. The Institute of Medicine has had a Task Force on Primary Care, trying for 18 months to develop a workable definition. The American Board of Medical Specialties also has such a committee.

As long as the flow of national resources is so heavily in the direction of tertiary care, it is tempting to dismiss all such activities as meaningless or, at best, peripheral. Peripheral they certainly are at the moment, but it is my conviction, based on underlying demographic and socioeconomic trends, that they will become steadily more important. Just as chronic illness, including mental illness, has moved to center stage in the nation's morbidity and mortality picture, so the health care modalities that are directed at the prevention and management of chronic illness will, almost inevitably, become more important.

For the moment this constitutes a prime example of an area in which the health professions and the industry are receiving conflicting signals from the public. It is also an area in which the professions can help the government adjust its policies to the realities of current morbidity and mortality patterns and trends. Only after such adjustments are made and we come to some agreement on common goals can meaningful public accountability take place.

Cost Controls

Money is obviously a key issue in the provision of health services. Financial considerations influence both the direction of public policy and the interactions between public and private sectors. APA has put the proposition succintly: "The dollar flow is not merely a disbursement mechanism. It is a management tool which can be used for good or ill (17).

Prodigious inflation of health care costs has persisted for three decades, bringing health expenditures to well over $150 billion this year and moving rapidly toward 10% of the GNP (14, p. 3). The amount is so staggering that it is difficult to comprehend. Two comparisons may be helpful: 1) We are spending more for health care in the United States than the entire GNP of all but half a dozen other nations (18, p. 845). In 1973, the last year for which I have comparable data, we spent $95 billion for health care compared with $13 billion for the entire criminal justice system, including police, the judiciary, and prisons (14, p. 4; 18, p. 160). With homicide now our fastest rising cause of death (19, p. 26), the question can legitimately be raised whether the health of the American people might not now be better served by putting additional resources into law enforcement rather than health care.

Far from any sign of abatement, however, the rate of health care inflation has accelerated during the past few years. The rate during the past year is three times that of the general cost of living (20). Concern has understandably deepened. The causes are multifaceted and deeply rooted in both supply and demand factors. The phenomenon of rising costs prevails, in greater or lesser degree, in most advanced countries, regardless of varying methods of financing. This fact underscores the difficulty of establishing effective controls, particularly in a democracy.

There is a hen-and-egg relationship between the cost rise and financing mechanisms. The rise in costs led to the development of public and private health insurance, governmental health services, and other methods of minimizing the financial barriers to needed services. However, the very existence of such programs contributed to further cost rises. More programs were then added or existing programs expanded to meet the new hardships.

Most advanced countries have carried this process to the point of universal or near-universal coverage. Ironically, the United States, the richest of all countries, has stopped short of universality—some 25–35 million people short. That is the approximate number estimated to lack any reliable access to health care, either through private insurance, Medicare, or Medicaid, or whose coverage is so thin that it is useless except in cases of serious hospitalized illness (9).

For several years it appeared that this gap in coverage would be closed through some form of national health insurance that would assure universal access to at least the basic components of comprehensive care. However, the level of inflation, especially in hospital costs, that has prevailed since 1974 has dashed this expectation. As Dr. Gibson said in his Presidential Address, "Alarmed by runaway costs, legislators are hedging on the original declaration that health care is a right" (1). This appears to be a bipartisan judgment on

the part of both Congress and two successive Administrations.

It is hard to quarrel with the conclusion in terms of competing demands on national resources from other essential sectors of the economy that also affect health. Nevertheless, it has to be a matter of acute embarrassment to both public and private leaders of the health care "Establishment" that we in the United States have failed to hold the rise in costs within dimensions that would make universal coverage possible. It is, of course, the poor, whose clinics and neighborhood health centers are being closed; the aged, who are forced unnecessarily into inadequate nursing homes for lack of home care services; and the mentally ill, who still have to be institutionalized for lack of adequate community mental health programs, who are paying the price for the inordinate rise in costs and our inability to control it.

Here again, however, the medical profession is getting mixed signals from government. On the one hand, there are the daily scoldings and exhortations to control costs, the periodic release of names of physicians alleged to have profiteered from government payments for health care, and proposals to establish "caps" or ceilings on the annual increases. On the other hand, there is the failure to provide adequate support for primary and long-term care and the Medicare blank-check reimbursement policy for inpatient somatic illness.

This is not the place to undertake discussion of all that would be involved in establishing an effective program of cost controls; nor is it germane to my main thesis. Such a program would have to be as multifaceted as the causes of the inflation. Whatever the specifics, however, there are two essential components: 1) It will have to put an end to the current bias in favor of inpatient, technologically dominated care. 2) It will have to have input from the leadership of the professions and the industry, input that is not limited to protecting special group interests but is attuned to broad national needs and concerns, is prepared to think in terms of the public interest, and is prepared to live with the consequences without being constantly policed. This would be public accountability of the highest order.

Prevention

Despite the obvious "commonsense" proposition that preventing illness is good not only for health but also for the pocketbook, we have relegated prevention to a very low rank on the national health priority list. Estimates of the proportion of national health care expenditures going for prevention vary from 2% to 5%, depending in part on definitions (21, 22). For health education the proportion is probably less than half of 1%.

There are many reasons for this neglect, some of which have already been suggested: the skewing of resources toward tertiary care and the prevailing pattern of health care financing. The current financial crunch now gives rise to another major irony. Advocates of prevention have maintained for years that its neglect would lead to inordinate rises in the cost of curative medicine. They were correct. Now that that has happened, they are told that there is no money to help finance new preventive programs. This is true at all levels, federal, state, local, and institutional. Physicians who want to practice preventive medicine, who want to hold down hospital utilization and expensive therapies, are told by the U.S. Government: "Sorry, Doctor, but Medicare doesn't cover periodic health exams, or refractions, or preventive dental care, or preventive psychiatric counseling. . . . However, when your patient is hospitalized, that's a different story. We'll pay for whatever you want to do."

It is easy to make fun of the third parties. They are sitting ducks for such criticism. But what of the profession itself? Are most physicians really concerned with "health" or just with their special disease or condition? Perhaps just with the biomedical facets of that condition? I have already made clear that the individual bears the primary responsibility for his own health. But surely there is also a large role for the physician. Although he cannot be a specialist in all of the areas that affect individual health, he can be expected to have more than a layman's concern and knowledge as to how these areas affect his own patients. Applying the "health field" concept, this would call for some knowledge of biological, environmental, and behavioral factors in the patient's history, as well as a plan for incorporating preventive services—both primary and secondary—into the patient's regimen.

The "Lifetime Health Monitoring Program" (LHMP), developed by Dr. Lester Breslow and myself (23), represents an effort to move toward a practical, affordable program that could be incorporated in most primary care practices and in public and private health insurance coverage. Using clinical and epidemiological criteria, LHMP attempts to define broad health goals and professional preventive services appropriate to 10 different age groups covering the life cycle. For two of these age groups, infancy and older middle age (40–59), we suggest specific screening and counseling procedures intended to help the patient achieve the defined goals.

The response to this article from both the medical profession and a number of health insurers has been so good that I am led to believe this may indeed be an idea whose time has come. Several groups are considering demonstration and evaluation projects. This is a form of public accountability that goes beyond the current official definition of public policy and takes into account underlying needs and developing trends. Thus it helps to mold future policy.

THE CHALLENGE TO PSYCHIATRY

If the concept of public accountability and the general redirection of U.S. health policy suggested in this

paper are correct, it would seem—at least to an outsider like myself—that psychiatry should be in an exceptionally strong leadership position vis-à-vis the health professions as a whole. This should be true whether one thinks in terms of individual patient care or national policy direction.

There appears to be a clear affinity between the comprehensive, holistic, biopsychosocial approach to patient care, implicit in recent articles by Drs. Marmor (2), Eisenberg (24), and Engel (25), and the comprehensive, balanced approach to national health policy recommended by Lalonde, Herman Somers, myself, and others. A balanced system of comprehensive care would place equal emphasis on primary, long-term, and tertiary components; ambulatory as well as inpatient care; and physical and mental illness. Under effective cost restraints that do not favor one modality over others, specialties that are less dependent on expensive inpatient facilities and equipment would obviously be in a stronger position than they are now. Specialties that emphasize individual and community responsibilities rather than expensive technological interventions would also gain.

I believe this is consistent with the position of psychiatry, which, for two decades, has emphasized the importance of "getting out of the hospital and into the community." The national network of community mental health centers, whatever their current shortcomings, stands as a monument to this leadership and represents an essential aspect of primary care.

I am not suggesting any repudiation of scientific medicine, that indispensable storehouse of knowledge which has been so painstakingly and often painfully accumulated over the centuries. I am suggesting that the public need for more attention to the psychosocial aspects of health and the renewed interest in prevention present psychiatry with a golden, perhaps unprecedented, opportunity in such crucially important areas as drug and alcohol addiction, obesity, television and the "culture of violence," human sexuality, the disappearance of the extended—and now possibly even the nuclear—family, the loneliness of the aged and the dying, the grief of survivors, the increase in illegitimate births, and child abuse. Many of psychiatry's traditional and special concerns are now among the central health concerns of the American people.

Of course, concern is not enough. Again to cite Dr. Gibson, the fact that many existing procedures and therapies are accepted and reimbursed by society, without requirement as to cost-effectiveness, is no excuse for psychiatry to try to play the same game. The ground rules are becoming tougher all around, and psychiatry, like somatic medicine, has to face the demand for refinement of standards and criteria, more valid outcome studies, better peer review, and other proofs of efficacy. The emphasis being placed on peer review in recent APA publications and policy statements and APA's initiatives in this respect, if actually implemented, seem to me good examples of increasing accountability. The new multidisciplinary peer review contracts, currently being negotiated with the Department of Defense for the CHAMPUS program, could be an important precedent for the profession as a whole.

The other side of the coin is fair and adequate funding. Experience in Canada and under the U.S. Federal Employees Health Benefits Program indicates that equal treatment for mental and physical illness need not result in abuse of psychiatric benefits or exhorbitant costs. After some 15 years' experience, the proportion of total benefit payments (high and low options combined) spent on mental illness under the largest plan participating in the federal employees' program appears to have leveled off at a little over 7% (26, p. 12). In Canada, where mental disorders are covered fully on the same basis as other conditions, the per capita payments in the early 1970s varied from $0.43 to $3.15, depending on the province, and from 1.4% to 5.4% of total payments (26, pp. 13–14).

Despite such evidence, mental illness and psychiatry have been notoriously shortchanged in both public and private health insurance programs in the United States. According to APA figures, about 20% of all persons with hospital coverage and 15% of those with physician outpatient coverage still lack benefits for mental illness (26, p. 11). Moreover, when benefits are provided for mental illness they are generally more restricted than those for physical illness. This was true, for example, of 70% of the Blue Cross plans. Probably the most egregious example of discrimination is in Medicare: Outpatient psychiatric benefits are limited to an annual maximum of $250 or 50% of "reasonable charges," whichever is less, after a $50 deductible. This, of course, reflects Medicare's bias not only against mental illness but against preventive services in general.

Over the years general tax support has helped to compensate for the inadequacies of health insurance. This support will almost certainly continue to be necessary for certain types of mental illness. However, the unpredictability of such funds, as presently administered, offers little incentive to consistent professional accountability, including effective resource management. Moreover, it is essential for quality controls that psychiatry be considered part of the mainstream of health care, not separated by some financial iron curtain.

Obviously, there are problems in the coverage of mental illness, e.g., the definition, the specificity of diagnoses, and evaluation of results. As in all of medicine, there are special problems relating to primary care, prevention, and long-term care. However, there are even greater problems in trying to ignore them. The $150 billion health care bill is not the result of abuse of prevention and long-term care; it is primarily the result of abuse of secondary and tertiary care. It is at least partially the result of neglect of prevention and long-term care.

I shall not attempt to lay out a program of reform of mental health financing. APA's "Principles of Psychi-

atric Coverage under National Health Insurance" appear a sensible beginning (26, pp. 4–5). However, since there now seems little chance of implementing any form of national health insurance for the next few years, I would strongly suggest that the Association direct its immediate attention and energies to the reform of Medicare and existing private insurance. This will mean trying to establish benefit and payment standards at the state, as well as the federal level, a time-consuming process, but well worth the effort. If successful, it will not only improve coverage for millions of patients in the immediate future but help to set the pattern for national health insurance when it does come. In this respect, I know that APA will be working closely with the President's Commission and its special panel on financing.

CONCLUSIONS

The challenges facing psychiatry in the next decade are enormous. A great deal will depend on the basic direction of health care policy as well as on APA's stewardship under that policy. If we persist in following the current high-cost "technological imperative," I see a bleak future for psychiatry, along with prevention, primary, and long-term care in general. The inevitable cost controls will probably be harsh and arbitrary, and many consumers as well as providers will suffer. If, on the other hand, we move gradually to reorient policy and resources toward a less technological and more people-oriented system, with equitable cost restraints developed and applied in a democratic but unambiguous fashion, and if we can rely on public accountability by a freely cooperating profession and industry, the future could be bright indeed—not only for psychiatry but for a revitalized and rehumanized health care system.

In this field, at least, the cherished "American dream" could take on a new meaning. The "limitless frontier" of the future would relate less to geographic, technological, and financial considerations than to the vast potential of the human spirit, a spirit as bold and free as that of the astronauts who walked on the moon but wise enough and humble enough to appreciate the wisdom of Hegel's version of the "categorical imperative": "Freedom is the recognition of necessity."

Diagnosis: Schizophrenia Versus Posterior Aphasia

BY STEPHEN N. GERSON, M.D., D. FRANK BENSON, M.D., AND SHERVERT H. FRAZIER, M.D.

Schizophrenia and posterior aphasia are easily cross-diagnosed, primarily because of similarities in verbal output, i.e., vagueness, looseness of association, and apparent confusion. Tape-recorded interviews with 8 posterior aphasics and 10 "loose" schizophrenics were transcribed and analyzed to provide guidelines for the clinician to differentiate the two conditions by monitoring verbal expression. Six major differentiating characteristics were identified. The authors present hypotheses that emphasize differing neuroanatomical loci and neuropsychological mechanisms to explain the differences in verbal output in schizophrenia and posterior aphasia.

SCHIZOPHRENIA and posterior aphasia are easily confused and cross-diagnosed, primarily because of similarities in verbal output, i.e., vagueness, looseness of associations, and "confusion." Although the verbalizations of the two patient populations have been characterized separately by many investigators, few studies have compared them in order to determine differentiating features.

In an earlier discussion we stated that

> When a patient with no apparent neurological disturbance produces words easily and in grammatically acceptable combinations, but the output is not comprehensible to the examiner, a diagnosis of abnormality of thought content may be entertained. If in addition, the patient reacts negatively or not at all to the examiner's verbalizations, he may be considered to be out of contact and a diagnosis of psychotic breakdown may be entertained. The above state, however, accurately describes a posterior aphasia. (1, p. 558)

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

When this work was done, Dr. Gerson was Research Fellow in Neurology at Boston Veterans Administration Hospital and at Boston University School of Medicine; he is now Director of Psychiatry, Lorain Community Hospital, 3700 Kolbe Rd., Lorain, Ohio 44053. Dr. Benson is Chief, Neurobehavioral Center, and Professor of Neurology, Boston University School of Medicine. Dr. Frazier is Psychiatrist in Chief, McLean Hospital, Belmont, Mass., and Professor of Psychiatry, Harvard Medical School.

This work was supported by Alcohol, Drug Abuse, and Mental Health Administration grant 5-F22-MH-00953-02 from the National Institute of Mental Health to Dr. Gerson and by National Institutes of Health grant NS-06209 from the National Institute of Neurological Diseases and Stroke to the Boston University School of Medicine.

Because of this verbal behavior and absence of general neurological findings, the posterior aphasic is frequently referred to the psychiatrist, who must differentiate the neologisms, reiterations, pauses, comprehension disturbances, circumlocutions, verbal substitutions, and intrusions of the posterior aphasic from those seen in schizophrenia. Broca's and other anterior aphasias are easily distinguished (2), but separation of schizophrenic output from that of posterior aphasia is admittedly difficult and demands careful attention.

Descriptions of schizophrenic speech are abundant. Bleuler (3) described disordered quantity of verbal output (from press of speech to muteness), blocking, altered intonation, inappropriate affect, inexact word usage, neologisms, condensations, loose associations, word salad, inappropriate ironic juxtaposition of trivial and important concepts, and perseveration. Lehmann (4) noted that disordered verbal behavior in schizophrenia included being overly concrete and overly symbolic, cryptic meanings with language as a means of self-expression rather than communication, neologisms, intermittent muteness, echolalia, verbigerating (senseless repeating of a word or phrase), and being overly stilted, pedantic, and formal. There have been several other descriptions in the literature (5–9).

Diagnostic errors are not surprising because, by habit and training, psychiatrists generate their diagnostic impression from careful attention to the *content* of the patient's verbal utterances, rather than the *quality* in terms of syntax, verbal substitutions, patterns of pauses, agrammaticisms, coherence of verbalizations, etc. Because of the confusing similarities in verbal behavior, posterior aphasics may be misdiagnosed and confined to mental hospitals. It is the purpose of this report to discover and accent those signs of verbal output that would aid the psychiatrist in establishing the correct diagnosis.

METHOD

Interview

The data consist of 15-minute tape-recorded interviews conducted as follows. The interview began with 7–8 minutes of open-ended questions, e.g., "What are you here for?" "Tell me about your favorite hobby." The patient was encouraged to continue talking if he/she stopped verbalizing. Included in the 7–8 minutes were the following directed questions: "What is your

name?" "Where are we now?" "What kind of work do you do?" "Where were you born?"

Subjects

Two diagnostic populations were interviewed. All diagnoses were based on criteria listed below in addition to the diagnosis of the attending physician.

The posterior aphasic group consisted of 8 patients with fluent paraphasic verbal output, i.e., Wernicke's aphasia, transcortical sensory aphasia, or conduction aphasia (2). Criteria for the diagnosis of posterior aphasia depended on characteristic speech production plus confirmatory localizing information, such as neighborhood neurological findings, brain scan, or EEG localization of lesions in the appropriate areas of the dominant hemisphere.

Posterior aphasics produce abnormal verbal output characterized by fluent paraphasic speech. In addition, there may be problems in comprehension of spoken language, disturbances of repetition, serious word-finding problems, alexia, and/or agraphia to a greater or lesser degree. The onset is most often acute and accompanied by elementary neurological findings, but these may be transient, leaving abnormal language as the only residual. Cases with a slow, subtle onset of disordered verbal output are diagnostically treacherous. Appropriate laboratory tests may demonstrate pathology in the dominant temporal lobe or temporoparietal junction area. Each posterior aphasic in this series had both a diagnostic clinical picture and confirmatory laboratory tests.

The schizophrenic group consisted of 10 patients who were evaluated during acute schizophrenic episodes. Each patient was "loose" when tested, although most were medicated at the time of evaluation. Each patient had at least three of Schneider's first-rank symptoms (10). In cases where there had been laboratory tests such as brain scan and EEG, results were negative, and none of the subjects had evidence of elementary neurological dysfunction.

Characteristics of Verbal Output

The following features of abnormal verbal output (chosen from a review of the literature) were noted, tabulated, and compared: 1) appropriateness of response to the question; 2) syntactical pattern, i.e., blocking, pauses, verbigeration, stiltedness of language; 3) tendency to reiterate; 4) comprehension defect; 5) abnormal verbal content, i.e., a persistent theme controlling verbal output, such as an internalized pattern of thought; 6) circumstantiality; 7) circumlocution; 8) echolalia; 9) perseveration, i.e., repetition of a word, phrase, or action used in response to a previous question; 10) neologism; 11) paraphasia, i.e., the substitution of an incorrect word or letter in the output; 12) detailed responses, i.e., redundant, excessive, and inefficient verbalization; 13) condensation; 14) alliteration; 15) onomatopoeia; 16) clang association; 17) intonation defect, i.e., inappropriate affect for the content of the response; and 18) novel characteristics not otherwise described.

The tapes were analyzed independently by two judges who used the list of characteristics described.

RESULTS

Some of the 18 characteristics were of no help in differentiating the two disorders, but others did help in establishing the correct diagnosis.

Appropriateness of response to questions was not helpful. Both schizophrenics and posterior aphasics gave inappropriate responses about 40% of the time, presumably for different reasons. The schizophrenics appeared to be attending to an internal preoccupation, while the posterior aphasics perseverated or failed to comprehend the question.

Analysis of syntactical patterns was of only limited usefulness. Blocking was marked in both groups; stuttering (machine-gun repetitions of the initial phoneme of a word) was frequent in posterior aphasics but occurred only occasionally in schizophrenic output.

A tendency to reiterate or repeat words and phrases was noted in both groups. The schizophrenics tended to reiterate delusional themes when allowed to respond at length. Posterior aphasics repeated words and short phrases, e.g., "But actually, a real rattler has tiny, little, tiny little, uh be . . . be, bey, bey, uh, uh, things, you know." Comprehension problems were also present in both groups but were qualitatively different. Posterior aphasics often comprehended the first few questions but then appeared to "jam" or fatigue. If the examiner could gain the schizophrenics' attention, they comprehended.

Persistent themes appeared to modify and control the verbal outputs of both groups. Schizophrenics were often preoccupied with delusional concerns that intermittently penetrated their response; if the posterior aphasics stuck to one subject, it was a perseveration or failure to change set. The posterior aphasics were circumlocutory while the schizophrenics were circumstantial.

Echolalia was absent in both groups, as were condensations. Schizophrenics did not perseverate, whereas 70% of the posterior aphasics perseverated at some point in the interview. Neologisms were not found in any of the schizophrenics' output. Paraphasia was present in posterior aphasics and absent in schizophrenics. Informational detail was far less in posterior aphasics than schizophrenics, which probably reflected frequent pauses and relative paucity of substantive nouns in the posterior aphasics (substantive nouns accounted for only 3% of that group's output compared with 11% of schizophrenics' output). Alliterations and onomatopoeia were absent in both groups and only 3 of 10 of the schizophrenics demonstrated a rare clang association (1/3000 words). Both groups behaved inappropriately and gave inappropriate responses in ways that were different and characteristic.

Six striking differences in the verbal output of schizophrenics and posterior aphasics were noted. First, the responses of the schizophrenics to the open-ended questions were considerably longer. Individual responses of the posterior aphasics averaged between 20 and 30 words, whereas the schizophrenics' ramblings were typically 100 or more words. The posterior aphasics would pause or look to the examiner for a response or another question after a brief machine-gun-like output of fluent, empty phrases. In contrast, the schizophrenics often produced extremely long responses (700–800 words), stopping only when interrupted by the examiner's next question.

Second, the posterior aphasics demonstrated *some* awareness of their expressive difficulties and were disturbed by it, whereas the schizophrenics either presumed the interviewer understood their vague utterances or were unconcerned about the adequacy of communication. Even relatively recent (i.e., 1–2 weeks after a cerebrovascular accident) severe posterior aphasics demonstrated some awareness that something was awry. As they improved, they became increasingly aware of their problem. Conduction aphasics (the posterior aphasics with the best comprehension) were the most concerned, but even they demonstrated a mild, inappropriate euphoria (lack of concern and awareness), a trait that was most pronounced in those with Wernicke's aphasia.

Third, the posterior aphasics often used nonverbal substitutes or pauses to enlist the aid of the examiner in overcoming word-finding difficulties. In contrast, the schizophrenics' pauses were effortless and autistic, and the examiner did not feel a pressure to offer assistance. Thus, the examiner's subjective feeling was one of pressure to help or relate to the posterior aphasic, but the nonrelating style of the schizophrenic tended to lull the examiner into inattention. The impression that the posterior aphasics were more concerned about their ability to communicate is enhanced by their increased use of nonverbal gestures, i.e., body motion and facial movement.

Fourth, substitutions of incorrect letters, words, or even an occasional neologism were common in posterior aphasia but rare in schizophrenia. In fact there were no neologisms or other paraphasias in our samples of schizophrenic speech. This total absence of neologisms is striking, since most textbooks list neologism as a characteristic of schizophrenic output. All of our posterior aphasics produced neologisms, but they were uncommon (about 1/500 words); other paraphasic substitutions were common, occurring as often as 1/15–20 words.

Fifth, vagueness of response was prominent in both disorders but was clearly derived from different sources. Aphasic vagueness arose from word-finding difficulty. Posterior aphasics produced a comparatively voluminous output with relatively few substantive words. Brief pauses were frequent in the posterior aphasic's output, occurring most often when a substantive noun was indicated. This word-hunting quality differentiated the posterior aphasics' pauses from the thought blocking of the schizophrenics. Thought blocking was not frequent in our sample of schizophrenics, and pauses were less frequent in schizophrenics than in posterior aphasics. The schizophrenics produced a comparatively full lexicon, with shifts in subject matter during speech, apparently secondary to alterations of attention that resulted in incomplete, approximate, and vague responses.

Finally, the difference in content of the output was notable. The schizophrenics produced bizarre themes that were repeated; two or three persistent themes would be reiterated throughout the 15-minute conversation. In contrast, while the posterior aphasics' content presented many repetitions and intrusions, there was no persisting theme, and over the 15-minute interval many disparate themes were introduced.

DISCUSSION

The observations we have presented demonstrate basic differences in the verbal output in the two disorders. The differences can be readily noted by auditing verbal output and may be used to assist diagnosis.

In clinical practice the examiner often has anamnestic information to aid in making a correct diagnosis. For example, loose schizophrenics are usually younger, i.e., in their 20s, than posterior aphasics, most of whom are over 40. A premorbid personality aberration frequently precedes overt schizophrenia. Posterior aphasics may have no such history; rather, they suffer an acute onset of altered behavior. There are situations in which an adequate history is not available and, of course, both disorders can occur at any age. In problem situations attention to the following six characteristic features can prove helpful. In most cases when one differentiating feature was noted, the others were also present.

1. Length of response is shorter in posterior aphasia.
2. Awareness of communication problem is greater in posterior aphasia.
3. Efforts to enlist examiner's aid in communication occurs in posterior aphasia but not in schizophrenia.
4. Substitutions in language (paraphasias) are common in posterior aphasia and rare in schizophrenia.
5. Vagueness of response is present in both groups, apparently due to word-finding problems in posterior aphasia and to attentional disturbance in schizophrenia (circumlocution versus circumstantiality).
6. Content—bizarre themes are present in schizophrenia but absent in posterior aphasia.

Finally, some comments on the theoretical implications of the underlying mechanisms and neuropathological correlates of the two disorders may be heuristically useful. Expressed most simply, the verbal output of the posterior aphasic is a disorder of language, whereas that of the schizophrenic derives from a disorder of thought. Differentiation of abnormalities of

verbal expression into speech, language, and thought disorders (11) can be outlined as follows. A speech disorder is a distortion of otherwise adequate verbal output caused by neuromuscular disturbance involving some part of the speech mechanism. Patients with a speech disorder know exactly what they want to say, but mechanical disturbances interfere with output. Examples include stuttering, extrapyramidal dysarthria, etc. A language disorder is an abnormality of verbal output in which the patient has difficulty manipulating the semantic and syntactic structures necessary to express his ideas; all aphasics have language disorders. A thought disorder is the expression of abnormal ideas through intact language functions. Thus thought disorders represent abnormalities of ideation that are reflected in verbal output. Examples of disordered thought include overly concrete thinking, personalized thinking, idiosyncratic or bizarre thinking, obsessions, phobias, intellectualization, thought withdrawal, thought insertion, thought broadcasting, delusional percepts, overly symbolic thought, dereistic thinking, and magical thinking. Denial, projection, paranoia, circumstantiality, and tangentiality are disorders of thought that are often present in organic mental problems.

Maher (8) contends that normal coherent speech is the result of a successful and instantaneous inhibition of associations to each element in the utterance. A sentence is an extremely complex act demanding continuous inhibition of distracting associations, a process that breaks down in schizophrenia. On the other hand, disruption of syntax, almost a hallmark of aphasia, is rarely found in schizophrenia.

Stevens (12) proposed a subcortical neurological focus for disordered thought in schizophrenia. She hypothesized a breakdown in neostriatal and limbic striatal "gates" ("filtering structures") interposed between the cortical mantle and afferent fiber tracts of the motor, sensory, and visceral systems. Hyperattentional states may occur in schizophrenia when the gate is "overwhelmed" and normal inhibitory abilities are diminished or lost. The patient cannot keep competing stimuli and associations out of consciousness. Coherence of thought and, thus, the patient's sense of continuity and identity are disrupted. Disorders of thought appear to result from malfunction of subcortical CNS activities.

Unlike the disordered verbal output of schizophrenia, which appears to derive from subcortical dysfunction, aphasia results from damage to the cortex (of the dominant hemisphere). Geschwind elucidated the mechanism of posterior aphasia as follows:

> Broca's area is a way station between Wernicke's area on the one hand and the neurons which send axons to the motor nuclei of the speech organs on the other. However, it is more than an intermediary way station. It seems that it contains the rules for turning the sounds of speech into motor acts. It might be called an auditory-motor transducer. (13, p. 189)

Wernicke's area (the auditory association cortex) acts to classify the auditory input into patterns. These patterns, when passed forward, elicit activity in Broca's area to produce the motor activities for speech. Broca's area is, to some extent, controlled by stimuli from Wernicke's area. When the latter is destroyed or disconnected, Broca's area may run on freely, without normal inhibition. The resulting verbal output is fluent, well-articulated speech because many of the sequences of language are overlearned and Broca's area can run on without control. Thus, in a sense, the fluent output of posterior aphasia also results from decreased inhibition. In posterior aphasia, however, it is a lack of cortical control that leads to the disturbed verbal output.

Thus we can hypothesize that the abnormal verbal output of posterior aphasia derives from a cortical-cortical disruption while that of schizophrenia derives from a subcortical-cortical disruption. The six features that differentiate the output of schizophrenia and posterior aphasia would appear to be the differences between the underlying thought disorder in loose schizophrenia and the language disorder in posterior aphasia, which derive from different neuroanatomical disruptions.

A Study of Treatment Needs Following Sex Therapy

BY ALEXANDER N. LEVAY, M.D., AND ARLENE KAGLE, PH.D.

The authors describe 19 couples who returned for additional treatment after traditional short-term sex therapy. Eight couples required additional short-term sex therapy, and 11 couples were treated primarily with individual psychoanalytic psychotherapy or conjoint therapy for an extended period of time. The authors identify three reasons for return to therapy: 1) treatment overload, 2) severity of symptoms, and 3) presence of psychopathology relevant to the sexual dysfunction. They point out that pleasure, intimacy, and cooperation dysfunctions need to be worked through if sex therapy is to have lasting effects.

SINCE THE PUBLICATION of *Human Sexual Inadequacy* (1) the Masters and Johnson method of rapid treatment of sexual disorders has become widely practiced and acclaimed. Several modifications of the basic technique have been introduced, notably Schumacher's variation of the duration and intensity of treatment (personal communication from S. Schumacher) and Kaplan's departure from dual therapy teams to single therapists (2). Follow-up studies of these therapies so far have indicated that short-term treatment is highly efficacious and efficient and that gains made are essentially maintained for as long as five years (1, 2). Although published studies indicate that approximately 80% of all patients experienced symptom reversal and that few of these relapse, our experience suggests a more cautious judgment and calls for a more complex and comprehensive assessment of treatment results. In particular there is a need for detailed study of long-term symptom reversal and improvement.

This paper will attempt to evaluate the effectiveness of treatment by describing and analyzing the results of the treatment of 19 of 45 couples who were originally seen for classical two-week Masters and Johnson therapy (1) and returned on their own initiative for additional treatment with one of us (A.N.L.) because their sexual adjustment had deteriorated or failed to progress. The first phase of treatment was conducted by a dual sex cotherapy team of psychiatrists who had received formal training in sex therapy at the Reproductive Biology Research Foundation in St. Louis. The second phase of treatment consisted of individual or conjoint therapy or both as indicated by the needs of the couple and was conducted by A.N.L. alone or by referral.

METHOD

Phase 1

Between June 1971 and June 1973, 45 couples referred by themselves or their physicians/therapists for sex therapy were seen for two weeks in Masters and Johnson intensive sex therapy. Criteria for acceptance into treatment included 1) presence of a sexual dysfunction, 2) willingness to work out the problem as a couple, 3) motivation to work out the problem for one's own sexual functioning and pleasure, 4) the absence of prohibitive psychopathology and/or intramarital conflict, and 5) the absence of overwhelming reality or organic factors. All patients were private patients, mostly of upper-middle class background, and ranged in age from 19 to 69 years. Presenting problems included all the categories of sexual dysfunction reported by Masters and Johnson in a comparable distribution. After the 2-week treatment period couples were seen for follow-up at least twice, at 2 weeks and 2 months. In addition they were asked to return for a 1-year follow-up. Only 4 couples did so; 3 are among the 19 reported here.

Of the original 45 couples, 10 cases were judged to be unimproved or deteriorated. In all the remaining 35 cases there was some degree of improvement or complete symptom reversal after the 2-week treatment period. Others in the field have reported similar results (1, 2).

Phase 2

After the termination of the original 2-week treatment period, 19 of the 35 improved couples (54%) returned of their own volition for further therapy with A.N.L. These couples left short-term treatment at all stages of improvement. In all cases the couples described a deterioration of sexual functioning or a fail-

Presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Levay is Assistant Clinical Professor, Department of Psychiatry, Columbia University College of Physicians and Surgeons, and Collaborating Psychoanalyst, Columbia University Psychoanalytic Clinic for Training and Research. Dr. Kagle is a clinical psychologist in private practice in New York City. Address reprint requests to Dr. Levay at 4 East 89th St., Apt. 5E, New York, N.Y. 10028.

The authors wish to thank Virginia Lozzi, M.D., Associate in Clinical Psychiatry, Columbia University College of Physicians and Surgeons, cotherapist for all 45 cases described in this paper.

ure to progress in the period following treatment as their reasons for seeking additional help.

During this second phase of treatment couples divided into one of two distinct treatment groups. Eight couples were seen in short-term follow-up treatment, which consisted of additional sex therapy. This first group was characterized by the ability to progress as a couple out of treatment. In each case the deterioration or lack of further progress was accessible to treatment within 10 sessions or less. The other 11 couples failed to respond to a second course of sex therapy and were seen either together or individually for more extensive and traditional psychotherapy. This second group was notable in that in every case there was moderate to severe underlying psychopathology and/or unconscious conflict, which required additional therapy exceeding 50 treatment hours.

RESULTS

Since becoming sexually functional is structured as a step-by-step process in sex therapy, we have chosen to subdivide improvement into five major stages plus a sixth category for individuals who are totally dysfunctional: stage 0, nonfunctional—no sexual desire; arousal, or sensation; stage 1, the identification of pleasurable sexual sensations along with discernible arousal, i.e., erection for the man and lubrication for the woman; stage 2a, the ability to experience sustained arousal and orgasm by self-stimulation; stage 2b, the ability to experience sustained arousal and orgasm by self-stimulation in the presence of one's partner; stage 3, the ability to experience sustained arousal and orgasm by manual or oral stimulation by one's partner; stage 4, the ability to function satisfactorily and experience orgasm in intercourse; stage 5, the ability to integrate stage 4 level of sexual functioning into one's normal life routine on a regular basis.

All 19 couples were evaluated according to these stages at four different points: before treatment, after phase 1 treatment, before phase 2 treatment, and after phase 2 treatment. In terms of sexual functioning, the initial level did not prove to be a predictor of long-term treatment outcome, with the possible exception of a tendency for couples consisting of a sexually functional man married to an anorgasmic woman to require long-term additional treatment. There was also a trend which suggested that couples in which both partners could masturbate to orgasm before treatment had a simpler course of therapy. However, these findings may be an artifact of the small sample size.

An analysis of outcome performed after phase 1 and also before phase 2 and the results after phase 2 therapy were also not useful in determining whether a couple would require short- or long-term additional treatment. Thus, it seems clear that it is not possible to depend on the level of sexual functioning alone in developing a treatment plan for couples requesting sex therapy. What is predictive is the degree of psychopathology: moderate to severe underlying conflicts or marital discord were present in all couples who required long-term additional therapy.

DISCUSSION

Experience in the second phase of treatment (and with some 300 couples seen subsequently in modified sex therapy) indicates that for many couples the treatment format has to be individually tailored and integrated with one or more of the psychotherapies in order to bring about lasting results. Although the treatment of choice for some couples is sex therapy alone, others need additional help. Similar conclusions have been reported in the literature, notably by Kaplan and Sager (2–5).

Reasons for Return

We have subdivided the reasons for return to treatment by these 19 couples into the following categories that we feel are relevant to all couples seeking sex therapy:

1. *Treatment overload.* Some of the patients who returned had experienced sex therapy as too intensive and overwhelming. Two-week treatment had not allowed for the necessary assimilation and working through of basic concepts and new behaviors. As a result these couples were left with a combination of residual problems and uncertainty about treatment direction and goals that did not allow them to grow on their own or resulted in a relapse. Altering the rate and duration of treatment so that the assignment of tasks was more in harmony with the couple's ability to participate resulted in successful utilization of therapy.

2. *Severity of symptom(s).* When the presenting sexual dysfunction was severe and of long duration, the course of sex therapy was often, of necessity, extended. Even with a highly motivated and therapeutically adept individual, it is often asking too much to expect that all the developmental steps and assimilative tasks necessary to become fully sexual can be accomplished in a two-week period. Several couples returned for treatment primarily because they needed to have additional treatment time to work through these required stages. Needless to say, the situation is further compounded when both partners suffer from a dysfunction or when a spouse becomes dysfunctional near the end of treatment as a direct consequence of his/her mate's improvement. Given additional time, however, most couples can resolve these unforeseen problems.

3. *Presence of psychopathology.* Other problems occur if, in addition to the sexual dysfunction, psychopathology is present in one or both spouses. As was seen in the second group of couples who returned, unconscious, unresolved conflicts, various psychiatric syndromes, or emotional immaturity gravely influenced the course of treatment. In cases in which severe pathology is present, albeit latent, the sex therapy

can activate conflict, symptom formation, and even full-blown psychotic episodes. Similar experiences have been reported by Kaplan and Kohl (6) and Meyer and associates (7).

Treatment procedures can be seen as a series of diagnostic tests in which the therapeutic tasks bring out relevant problems with great intensity and clarity. For instance, the need to maintain a parent-child relationship is brought into focus when a couple is asked to interact on a reciprocal basis. Similarly, anxiety reactions have been experienced following a first orgasm by individuals who have clearly exceeded both their superego limitations and ego ideal expectations.

If psychopathology is present in one or both partners, one of three outcomes is possible. For some people the successful completion of a specific sexual task, combined with the powerful emotional backlash reaction that often occurs, somehow serves as a corrective emotional experience and leads to profound insight into the dynamics of the sexual dysfunction. From then on resolution of the unconscious conflict and integration of the newly found sexual gains take place with surprising ease and rapidity. It is important for the therapist not to mistake these dramatic events for an incipient decompensation of the individual or failure of treatment but to support fully and facilitate this process to a successful termination.

Unfortunately this does not occur often. Instead, even without a breakthrough the emotional backlash to the sex therapy is of such magnitude and severity that it requires the temporary or prolonged suspension of this phase of treatment while the intra- or interpsychic problems can be worked out. It helps if during individual or joint treatment the therapist is prepared to reintroduce the spouse and/or the sex therapy as soon as sufficient progress has been made. It is important that neither the patients nor the sex therapist sees this as a failure but, rather, understands that the sex therapy helped focus on problem areas that required work before further sexual progress could be made.

The third possible outcome in cases involving psychopathology is a successful and seemingly uneventful course of sex therapy. This occurs when the dynamic underpinnings of the sexual problem are bypassed without resolution because of the very favorable conditions that sex therapy provides, including therapist support, expected superego relief, and a "honeymoon" atmosphere. All of these provide an ideal setting for a "flight into health" type of symptom reversal. These couples subsequently relapse and require an extensive therapeutic intervention similar to the couples already discussed, but they have the advantage of having already experienced what their sexual lives and marital relationship could be like once they work out their problems.

As we have already pointed out, the effect of such pathology on the course of treatment should not be overlooked or minimized. Although some claims have been made that psychopathology can be successfully bypassed in sex therapy, our experience in long-term follow-up indicates that stable results are only accomplished when and if the relevant intra- or interpsychic problems are resolved or at least reduced. This finding reinforces the importance of competence in diagnosis and broad training in psychotherapy in order to adequately treat sexual dysfunctions.

It is interesting to speculate about the 15 improved couples and the 10 treatment failures who did not return for the 1-year follow-up or additional therapy. Although it is not surprising that the latter group did not reenter a therapy they did not find helpful, we are looking forward to the results of a follow-up study of the entire sample in order to determine their subsequent course of therapy, if any, and their present state of sexual functioning.

Problem Areas

Finally we would like to comment on three factors that have been present alone or in combination in all of the 11 couples who required extensive further therapy. In fact it is useful for treatment purposes to categorize individuals seen for sex therapy not only in terms of presenting sexual diagnosis but also in terms of these factors, since they seem to play a key role in perpetuating sexual dysfunction. We see these as impairments in specific ego functions and have labeled them as problems in the areas of pleasure, intimacy, and cooperation.

Pleasure dysfunctions are primarily associated with an inability or difficulty in identifying, experiencing, and/or enjoying pleasurable sensation, i.e., difficulty in having sex for oneself. Pleasure dysfunctions often respond well to standard sex therapy, at least initially, since the treatment offers techniques for dealing with the lack of attention (low arousal) or overattention (spectatoring) often associated with this condition and also provides superego relief. However, when sexual activity is no longer monitored by the therapists, patients often regress or relapse.

Intimacy dysfunctions are primarily associated with inability or difficulty in experiencing and/or enjoying closeness, binding, and union with another person. Such individuals often find it hard to carry out the prescribed activities of sex therapy that focus on the mutual aspects of sexuality. Here difficulty is associated with having sex with another person. Again short-term treatment provides techniques for dealing with these blocks, but when the couple's intimacy is no longer supported as well as diluted in treatment by the therapists, relapse is likely to follow.

Many variants and varieties of marital discord are subsumed under the label of cooperative dysfunctions. The primary aspect of this factor, however, is an inability to collaborate, act as a team, or agree on common goals, priorities, or values. Although pleasure and intimacy dysfunctions can be unilateral, cooperative disorders almost invariably involve both spouses. Often what underlies this condition is a need by both partners to compete with or deprive each other, usually accompanied by other manifestations of transfer-

ential rage and retaliation. Giving to the partner sexually, or in other ways, is experienced as a loss or defeat. This can be described as a difficulty with sex for another person. Consequently, during sex therapy, pleasuring the partner is seen as self-negating, and treatment often becomes stalled when the task involves reciprocity. For these couples conjoint therapy is often essential before any meaningful sex therapy can get under way.

When these dysfunctions are found in combinations, treatment is much more difficult and time consuming. In our experience, stage 5 sexual functioning is impossible until all these areas of difficulty are worked through to a considerable extent.

CONCLUSIONS

Sex therapy is a powerful, effective, and efficient therapy. However, it is not a panacea. Work with 19 couples who returned for additional treatment following traditional short-term sex therapy served to highlight the types of residual problems that necessitated additional treatment. The presence of the type of psychopathology that blocked progression or maintenance of gains in sex therapy proved to be a differentiating factor between the 8 couples who required only short-term intervention and the 11 couples who required long-term additional therapy.

It is useful for treatment purposes to categorize patients not only in terms of presenting sexual diagnosis but also in terms of the types of psychopathology (of pleasure, intimacy, and cooperation) that interfere with progression in sex therapy. We have found that these dysfunctions need to be worked through if sex therapy is to have lasting effects. When these factors are present in combination or alone, sex therapy is a helpful but insufficient means for successful resolution.

Our experience indicates that sex therapy has to be further modified in order to maximize and stabilize gains for each couple. The treatment format needs to be open ended; flexible in the rate and sequence of task assignments; and, when indicated, coordinated or integrated with other psychotherapies, principally psychoanalytic psychotherapy and conjoint therapy.

On the Course of Anorexia Nervosa

BY REGINA C. CASPER, M.D., AND JOHN M. DAVIS, M.D.

The authors trace three phases in the course of anorexia nervosa and compare its physical and psychological symptoms with those of starvation. Phase I, which may occur months or years before the illness, usually includes precipitating events that result in loss of self-esteem and increased self-consciousness about physical appearance. During phase II patients develop the "anorectic attitude," an unreasonable fear of eating, and show pride in their ability to lose weight. By phase III patients are forced by the severity of starvation symptoms to admit that they are ill. Although many of the physical symptoms of starvation and anorexia nervosa are similar, anorectic patients, in contrast to victims of starvation, show high initiative, the ability to suppress hunger, restless hyperactivity, and body image distortion.

THE HISTORY of anorexia nervosa shows that it has not been difficult for the observant clinician to distinguish anorexia nervosa from starvation due to other conditions (1). A willful quality in the patient's refusal to eat and an insistance on thinness invariably associated with the emaciation led Gull (2) to conclude that "the want of appetite is due to a morbid mental state." Many physicians since the last century (3–7) have been fascinated by anorexia nervosa, yet few have seen and treated enough patients (8–11) to validly explore its psychological aspects.

When we were evaluating patients for a multicenter study designed to compare different treatment approaches to anorexia nervosa we noted that most of the patients' parents had initially mistaken the illness for a dieting fad, and many had remained unaware of a more serious problem until the child was markedly wasted. These observations led us to look closely into the natural history of anorexia nervosa. For this purpose we took a careful history of the sequence of events and systematically asked certain questions of both the patients and their families to trace the appearance and development of symptoms.

Furthermore, by talking to and treating hospitalized patients with anorexia nervosa we came to the conclusion that the effects of starvation are more intimately involved in the symptoms of anorexia nervosa than has been heretofore described. In order to define more clearly which symptoms are primary to anorexia nervosa rather than secondary to starvation, we compared the psychophysiological symptoms of starvation reported in the literature (12–18) with the symptoms shown by anorectic patients.

METHOD

Data were collected in evaluation interviews with approximately 30 patients who were referred for admission and their families and through observation of 20 hospitalized patients who were treated and followed after discharge in a larger collaborative treatment study supported by the National Institute of Mental Health (19).

Informed consent was obtained from the patients and their families after a detailed explanation of the treatment protocol.

Despite the fact that Feighner's diagnostic criteria for anorexia nervosa (20) contain some inaccuracies, such as classifying overactivity in the same category as bradycardia, they were used as an operational framework for the decision to include patients in this study (see appendix 1).

RESULTS

On admission patients had lost from 30% to 46% of their normal weight. Depending upon age and height, body weights ranged from a low of 26 kg to a high of 43 kg. The illness had lasted from 7 months to 6 years. All patients had been active in school, college, or work prior to admission. Only 2 patients were obese prior to weight loss. All patients were female.

We have found that conceptually dividing the course of anorexia nervosa into three phases is useful both in understanding the disorder and in the clinical management of patients. We believe that different symptoms and dynamics characterize each phase.

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Casper is Research Associate, Department of Research, Illinois State Psychiatric Institute, 1601 W. Taylor St., Chicago, Ill. 60612, and Assistant Professor, Department of Psychiatry, Abraham Lincoln School of Medicine, Chicago, Ill. Dr. Davis is Director of Research, Illinois State Psychiatric Institute, and Professor of Psychiatry, Pritzker School of Medicine, University of Chicago, Chicago, Ill.

The authors would like to thank the nursing staff of the 9 West Research Unit at the Illinois State Psychiatric Institute for their assistance.

Phase I

We systematically collected information on precipitating events and early symptomatology. External precipitating events that preceded the weight loss by months or years, such as siblings leaving the house, separation from or loss of friends, illness of a family member, going away to college, or getting married, could be identified in all cases. These events put the patient's self-esteem and self-concept to a severe test, resulting in painful self-doubt (e.g., "I felt I was not worth very much") along with feelings of powerlessness and loneliness.

This situation led patients to become preoccupied with themselves and more conscious of their physical development and appearance. Once they had attributed their dissatisfaction and general unhappiness to concerns about body size (most often about being "too chubby"), comments about a "round face" or a "tummy" were painfully remembered and dwelt upon and became the motive for the decision to diet vigorously. "If they don't like me as a person they cannot help but admire my body," said one patient; another stated, "This time I decided to really make it work." Although 3 patients lost weight accidentally through an illness and some patients used uneasiness after eating and vague sensations of fullness after meals as a pretext for reducing food intake, all patients stated that they had previously "had this idea in the back of my mind, to go on a diet."

Phase II

Most patients felt relieved and happier once they had begun to systematically and successfully reduce their food intake and had lost weight: "I had so much willpower, I felt so proud." It was also during this period that the anorectic attitude, an unreasonable fear of eating, became noticeable.

In order to highlight symptoms peculiar to the disorder, we wish to conceptually distinguish symptoms that could be secondary to starvation from those that occur only in anorexia nervosa. Anxiety related to food intake, expressed by the patient as a fear of becoming fat with each bite of food that effectively counteracts more or less continuous hunger feelings, is not observed in starvation but is pathognomonic for anorexia nervosa. Exactly when and how this fear develops could not be ascertained, although all patients said that they became aware of it after a certain amount of weight was lost.

Hunger awareness was reported by the majority of our patients (e.g., "I was hungry but it was so easy to pass up"). Patients could suppress hunger awareness quite successfully, particularly by exhausting themselves through exercise. Most patients complained after eating minimal amounts of food about feeling full and bloated yet not satiated or satisfied. Patients needed to consciously disregard this sensation of fullness in order to eat enough to gain weight. For many patients the sensation of an empty or full stomach, rather than normal feelings of hunger and satiation, seemed to be the primary regulator of food intake. One patient said, "The only feeling I wanted to feel was an empty stomach, and then I knew I was skinny." More important, all patients spoke about the pleasure and sense of achievement they gained from losing weight successfully; these feelings contrasted with their previous feelings of powerlessness and lack of enjoyment. As one patient put it, "I couldn't do many things, but I could do this."

Another symptom, which was first described by Bruch (11) and has never been reported in normal persons under conditions of starvation, is the failure of patients with anorexia nervosa to adjust their body image gradually to the progressive emaciation. Patients did not feel abnormally thin and consequently did not see any need for gaining weight. They typically said, "I don't see myself as really thin." It is surprising that patients without fail accurately perceive the emaciation of other patients with anorexia nervosa. As one said, "I can look at them, boy, they are really thin."

Appendix 2 compares behavioral and psychological symptoms observed during starvation states (12–15) with those of anorexia nervosa. Most of the information on starvation was gained during the Minnesota experiments on semistarvation (13). Although Keys and associates (12) used only young men recruited among conscientious objectors as subjects, the conditions under which the experiments were conducted came close to the situation involved in anorexia nervosa, in that the subjects were volunteers who were "starving in the midst of plenty." Most of the other literature on starvation (14–18) describes conditions in which subjects were not only deprived of food but also of their freedom and lived under severe duress.

As appendix 2 indicates, food restriction and a decreased caloric intake result in loss of strength and endurance accompanied by irritability and general discomfort. Subjects go through periods of increased worry and temporary depressive feelings, with a decrease in outside interests. This is not so in anorexia nervosa; when patients are lighter in weight they feel more vigorous, seem to have a reservoir of inexhaustible energy, and get involved in all kinds of activities. In fact, this restless hypermotility, which was present in all our patients, is a symptom regularly encountered in anorexia nervosa. Patients described a restless, sometimes exhilarating, feeling which prevented them from sitting still for a long time unless they were doing something. Restlessness and a quickening effect are sometimes encountered during food deprivation and are probably related to so-called appetitive behavior, which stimulates moving around. However, during starvation subjects generally attempt to conserve energy and reduce their activities, whereas anorexia nervosa patients continued to do exercises in order to lose weight. Anorexia nervosa patients pursue activities with a driven, almost obsessive quality; exercise programs are often highly structured and ritualistic, such

as doing exactly 150 rope jumps or 120 push-ups three times a day.

Another phenomenon that is typical in anorexia nervosa but is only reluctantly admitted by the patient is a constant preoccupation with thoughts of food or eating and difficulty concentrating on other matters. This has also been regularly experienced during prolonged fasting and is an expression of the strength of the hunger drive. Although the eating habits of both groups were strikingly similar (including the urge to handle food, cutting it into small pieces, picking at crumbs, and impulses to hide, hoard, or steal food), they were rationalized differently. During semistarvation these patterns were usually explained by a need not to lose out on any food. Anorectic patients, in contrast, usually complained that a meal was too large and stated that they found it easier to tolerate in smaller pieces; however, they could give no explanation for their urge to touch and handle food. Saving food during starvation seemed to give subjects an illusion of a safeguard in a situation over which they had little control. Anorectic patients called their hoarded food a "safety blanket" but felt ashamed and guilty about it, partly because they were aware that such behavior appeared senseless and unreasonable to others because they had access to an abundance of food. Another similarity between the two conditions is the occasional breakthrough of ravenous hunger feelings, sometimes with bizarre tastes and food preferences. Although daydreaming and fantasizing about food diminishes in starved persons when food intake is increased, in anorexia nervosa anxious ruminations about food and weight continue, with patients expressing fear that "one of these days I will wake up fat."

Phase III

Whereas patients who could accept treatment in Phase II were often successfully treated as outpatients, patients in phase III generally needed hospitalization. In this phase the patients' indifference to their bodily changes extended to all symptoms secondary to starvation and malnutrition. However, after a loss of 25% to 50% of normal body weight the effects of starvation (see appendix 3), such as hypotension resulting in dizzy spells, muscle wasting with weakness, hypothermia with blue and cold extremities, insomnia, amenorrhea, and hair and skin changes, had become so severe that patients eventually hesitantly acknowledged that there could be something wrong. At the same time, they still insisted that they did not feel thin. The arms were the only body parts perceived as wasted, probably because patients could readily inspect them and thus correct the mental image of their arms by visual perception.

Most patients during this stage made some ineffective attempt to eat more or stop regurgitation, but after a slight increase in meals and weight they panicked, frightened by the feeling that their bodies had become larger. They expressed the feeling that "Once you get started [eating], you don't know how to quit."

Despite their emaciation, patients denied any awareness or intention of self-destructiveness. Although some patients admitted that the thought that they might die had crossed their mind, all asserted that they did not want to die. Suicidal thoughts generally did not become conscious until the starvation process was reversed in treatment.

Since they were isolated from friends, struggling with their family, and weakened by malnutrition, patients had some difficulty in concentrating and in functioning; most, however, remained surprisingly mentally alert. We systematically asked anorexia patients during treatment if they had known beforehand that they would come to their present state by continuing to diet. They uniformly answered "no," thus indicating that they did not have full control over the process.

CONCLUSIONS

We have described three phases in the course of anorexia nervosa. The prodromal phase, which precedes the weight loss by months or years, is characterized by an emotional disequilibrium in reaction to traumatic events and eventually leads to the decision to restrict food intake. It is our impression that a process not unlike the one that precipitates the depressive syndrome may precipitate anorexia nervosa. Patients who develop anorexia nervosa make an active attempt to change their appearance instead of submitting to the depressive process. What apparently happens is that an initial disturbance in self-esteem eventually finds expression in a disturbed self-concept. Once the anorectic syndrome is fully developed, different psychological factors seem to be involved, but those contributing to phase I may again become important in the later stages of treatment.

Phase II marks the beginning of anorexia nervosa proper, with the development of an abnormal attitude, the "anorectic attitude," which is governed by fear on the part of the patient that she is in danger of overeating and becoming fat. The sequence of events reconstructed from the patient's history suggests that in predisposed individuals weight loss begun for psychological reasons could trigger anorexia nervosa through psychological and, possibly, biological mechanisms. Although the "hunger center" seems to be intact, a finding consistent with that reported by Garfinkel (21), the status of feelings of satiation is more difficult to ascertain. Thus there might be some dysfunction of the "satiety center." However, since disturbances in the perceptual transformation of the body image and the visceral sensations connected with hunger and satiety are so prominent, a suprahypothalamic disturbance appears more likely to be involved in these symptoms.

Despite many similarities between the psychological and behavioral manifestations of anorexia nervosa and starvation states due to other causes, characteristic features of anorexia nervosa such as fear associated

with food intake and the four areas of disordered body and self-perception described by Bruch (11) (absence of concern about even advanced emaciation, denial and disordered recognition of visceral sensations, lack of awareness of weakness and fatigue, and a paralyzing sense of ineffectiveness) have not been reported in starvation.

In phase III, starvation effects overshadow the anorectic symptoms. Although the absence of concern over the wasted appearance extends to all physical signs of starvation, there is also an increasing awareness of the abnormal physical state. This probably occurs because starvation effects reach awareness through bodily sensations; once these sensations become numerous and severe they cannot be repudiated by conscious experience as completely as the perception of the body image, which lacks a sensory equivalent. We found that in many cases directly pointing out to patients their true physical state was the only way to motivate them for treatment.

APPENDIX 1
Criteria for Diagnosis of Anorexia Nervosa*

1. Weight loss of at least 25% of original body weight or at least 15% below normal weight for age and height.
2. A distorted attitude toward food, eating, and weight, in particular, a pleasure in losing weight that overrides hunger, admonitions, reassurances, and threats; persistence in an idealized slim self-image and fear of gaining weight.
3. Amenorrhea of at least 3 months' duration.
4. Presence of physical signs such as lanugo, bradycardia, periods of overactivity, vomiting, episodes of bulimia, and hypothermia.
5. Absence of known medical illness or psychiatric disorder such as schizophrenia or major affective illness.
6. Onset between the ages of 10 and 30 years.

* Modified version of Feighner and associates' criteria (20).

APPENDIX 2
Comparison of Psychological and Behavioral Changes in Starvation and Anorexia Nervosa

MOOD OR FEELING STATE

Starvation: Lack of initiative; labile mood, quarrelsomeness; indecisiveness; deterioration of personal appearance; continuous hunger.
Anorexia nervosa: Initiative high; labile mood, alternating with feeling good; "strong-willed"; pride in personal appearance, occasional exhibitionistic tendencies; hunger present but easily suppressed.

MENTAL CONTENT

Starvation: Thinking and dreaming about food; concentration of interest on food with narrowing of unrelated interests; daydreaming, reading, and conversing about food.
Anorexia nervosa: Same as in starvation, but preoccupation with thoughts of food continues after weight gain.

EATING BEHAVIOR

Starvation: Bizarre tastes; preference for bulky foods and hot meals; dwelling a long time over meals; picking up crumbs; bulimia.
Anorexia nervosa: Same as in starvation, but low-calorie foods and fluids are preferred, and carbohydrates are avoided.

ACTIVITY LEVEL

Starvation: Fatigue; avoidance of physical exertion; restlessness and periodic quickening effect.
Anorexia nervosa: Seemingly inexhaustible energy; physical exercise sought; overactivity; restlessness with periodic quickening.

SEXUAL ACTIVITY

Starvation: Decrease in sexual fantasies, feelings, and interest; impotence; amenorrhea.

Anorexia nervosa: Same as in starvation; amenorrhea often precedes weight loss.

APPENDIX 3
General Effects of Starvation

Wasting of subcutaneous adipose and muscle tissue
Hypotension
Bradycardia
Hypothermia and increased tolerance to heat
Acrocyanosis
Loss of hair
Growth of "lanugo" hair
Constipation
Edema
Nocturia, polyuria
Sleep disturbances with early morning awakening

The Manfred S. Guttmacher Award

The American Psychiatric Association invites applications for its annual Manfred S. Guttmacher Award for 1978. The award is given for any outstanding contribution to the literature of forensic psychiatry in the form of a book, monograph, paper, or other work, including audiovisual presentations, submitted to or presented at any professional meeting or published during the period from November 31, 1976, to December 1, 1977. The award, which includes an honorarium of $250 and a plaque, will be presented at the Convocation of Fellows at the 1978 APA annual meeting in Atlanta, Ga.

Anyone who wishes may apply to receive the award by submitting five copies of the work as well as five abstracts to Carl P. Malmquist, M.D., Chairperson, Guttmacher Award Board, 1700 18th St., N.W., Washington, D.C. 20009. Entries will be acknowledged but will not be returned.

The deadline for submissions is December 1, 1977, and any entry to be considered must be in Washington by that date.

Revolutions and the Rights of Man

BY G.M. CARSTAIRS, M.D.

The author describes the dialectical struggle in psychiatric treatment between those who advocate maximum liberty in the management of the mentally disordered and those who believe such patients will benefit more from firm guidance and discipline. He uses illustrations from British psychiatric history to illustrate this struggle. He also points out and discusses two current challenges to psychiatry worldwide: the unconstructive hostility of the various schools of antipsychiatry and the political abuse of psychiatric diagnosis and treatment, particularly in the USSR.

THE HISTORY OF PSYCHIATRY is punctuated with revolutions and counterrevolutions. This is due to the fact that in both the area of theoretical understanding and the area of treatment policy antithetical schools have vied with each other for dominance. The contest has been between those who believe the basic underlying forces in mental illness to be spiritual, if not supernatural, and those who believe that ultimately all mental illnesses will be intelligible in pathophysiological terms. We all remember Hippocrates' challenge to the description of epilepsy as the sacred disease; he wrote, "It seems to me to be no more divine and no more sacred than other diseases but, like other affections, it springs from natural causes."

This dialectic continues in the rather sterile antithesis between those who place undue emphasis on either organic or psychological causes—as if either aspect can meaningfully be excluded. In this paper, however, I wish to concentrate on the dialectical struggle in the area of treatment between those who advocate maximum liberty in the management of the mentally disordered and those (not necessarily less benevolent in their motives) who believe that such patients will benefit from firm guidance and discipline. I will discuss this struggle with illustrations from British psychiatry.

FREEDOM VERSUS CONTROL

The antithesis between freedom and control can of course be recognized not only in psychiatry but in many other human activities as well. In the history of art it appears and reappears as the conflict between romanticism and classicism, between the Dionysian and the Apollonian schools. In education, it manifests itself in the contrast between clearly structured, disciplined teaching and the type of schooling that concentrates on eliciting the child's own interests as the motivation for study.

Until very recently the debate between advocates of "traditional" and "progressive" schooling was based almost entirely on the protagonists' personal preferences. In 1976, however, a controlled comparative study of primary schools in England (1) showed that the more traditional ones were significantly more successful not only in teaching children reading, writing, and arithmetic but also in eliciting imaginative work. The study also found that children in progressive schools showed higher levels of anxiety than did those in the more structured settings. All this was a rude shock to the advocates of permissive education, although they derived some consolation that the most progressive school studied was also the one whose students performed best on the formal tests of learning.

The debate about freedom or control in the management of the mentally ill has shown remarkable ups and downs. The eighteenth century, the Age of the Enlightenment, was a period in which educated people cherished unfettered intellectual inquiry as man's highest activity. Therefore, mental illness, which interferes with clarity of thought, was regarded as the supreme affliction. The eighteenth century was also the age in which two nations experienced a new crystallization of their views as to what are the essentials for human freedom and carried out successful revolutions in order to assert these values. The Declaration of Independence of the United States was dedicated to democracy. In spite of all its tribulations that ideal still thrives in the United States. The French Revolution took "Liberté, Egalité, Fraternité" for its slogan, but even before the revolution had run its course the revolutionaries were inflicting appalling cruelties on their fellowmen.

Thomas Paine, whose eloquence in defense of the rights of man contributed significantly to the events of 1776 in the United States, found that the Parisian revolutionaries initially welcomed his support, only to imprison him when he drew attention to their own violations of human rights. Robespierre himself had Paine's name put on the list of those to be purged. Even when in prison and threatened daily with a trip to the guillotine, Paine was able to write,

Presented as the keynote address of the 3rd International Film Festival, University of Texas Health Science Center, San Antonio, Tex., Oct. 22–24, 1976.

Dr. Carstairs is Vice-Chancellor, University of York, Heslington, York Y01 5DD, England.

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

> Painful as the want of liberty may be, it is a consolation to me to believe that my imprisonment proves to the world that I had no share in the murderous system that then reigned. That I was an enemy to it, both morally and politically, is known to all who had any knowledge of me; and could I have written French as well as I can English, I would publicly have exposed its wickedness and shown the ruin with which it was pregnant. . . . Imprisonment with preservation of character is preferable to liberty with disgrace.

(Have we not heard very similar assertions in recent years of the importance of human freedom from contemporary prisoners of conscience—Bukovsky,[1] Plyushch, Solzhenitsin, Fainberg, Sakharov, Roy and Zhores Medvedev, and so many others?)

In spite of its excesses, the French Revolution's initial drive for the liberation of the oppressed provided a favorable climate of opinion for Philippe Pinel's great reforms, symbolized by his striking off the chains from patients in the Bicêtre and the Salpêtrière in Paris. These reforms were applauded by liberal thinkers.

THE COURSE OF REVOLUTIONS

It is a curious facet of history that so many revolutionary movements begin with generous proclamations of brotherly love and sharing of all worldly possessions but end in bloodshed and injustices as bad as those which they set out to reform. This has been well documented in historian Norman Cohn's book *The Pursuit of the Millennium* (2). The millennial movements Cohn described all followed a similar course. They all began with sanguine prophecies of a new era of justice, equality, and brotherly love, in which plenty would be enjoyed without effort by all mankind or, at least, by the elect. As reality supervened and these magical expectations were disappointed, the movements became angry and violent and usually ended in bloodshed.

Cohn showed that irrational revolutionary movements have always occurred at moments in history when large groups of people found their settled mode of existence disrupted by sudden social or economic change. As a result, they were filled with uncertainty about their own personal future and that of their families. Cohn hypothesized that this sudden undermining of secure expectations made such groups receptive to the wish-fulfilling prophecies of mentally unstable leaders. However, Cohn's account is biased because by focusing on the recurrent fantasy of a new golden age he excluded other forms of adaptation to rapid change.

There have been many instances of organized groups, and sometimes whole nations, that have reacted to sudden change by adapting themselves realistically to the new social environment. Among such populations one must include the Russian and the Chinese people, both of whom have brought about new regimes that offer their citizens much better standards of living than they had before—but at the cost of enforced social conformity.

In Russia, those who are so rash as to dissent from the values of the regime run the risk of being declared insane and compelled to undergo psychiatric treatment. In China, according to the reports of visitors (3), the pressure to conform is evident even in psychiatric hospitals, where the mentally ill are involved in daily group discussions with staff and fellow patients. They are fully informed about their illness and about the treatments that have been prescribed, all of which seems commendable. However, they are also urged to view their lapse from rationality as an antisocial state from which they must try to emerge by self-examination and by studying the precepts of Chairman Mao.

LIBERTARIAN MOVEMENTS IN BRITISH PSYCHIATRY

It occurred to me to consider to what extent fluctuations of emphasis can be seen in the history of libertarian movements in psychiatric care in Britain during the last 200 years. The landmarks of any such review must be the new regimen of moral treatment, established in the Retreat at York in 1796; Dr. John Conolly's campaign for no restraint; the mid-nineteenth-century enthusiasm for occupational therapy; and the advocacy of open doors in the new county asylums built in the 1850s and 1860s.

Each of these landmarks was the work of a minority of enlightened individuals. The general standard of patient care in Britain left much to be desired, as was shown by Dorothea Lynde Dix when she toured British mental hospitals in the 1860s. Without exception the libertarian reforms lost most of their original impetus before the end of the nineteenth century, although one of the finest buildings in Edinburgh's Bangour Village Hospital, built as late as 1906, had carved in stone over its porch the brave words "curative workshops."

It can perhaps be argued that moral treatment, occupational therapy, and open doors declined because exaggerated expectations had been associated with their introduction. When expectations for reforms were more realistic the reforms continued to form part of the hospital regimen (as at the Lincoln Asylum, under Charlesworth and Gardiner-Hill, and at the Chrichton Royal Hospital in Scotland, under W.A.F. Browne).

Work in the fields and vegetable gardens attached to the nineteenth-century mental hospitals also formed part of the patients' regimen, but its therapeutic effect was blunted by the low level of skill expected of the patients, who found it a monotonous and unstimulating chore. However, in the 1930s interest began to revive in the effectiveness of a busy, well-planned pro-

[1]Since this paper was written, Bukovsky has been released to the West in exchange for a Chilean political detainee. He has made several public appearances; he has shown no evidence of being psychiatrically disturbed in any of them.

gram of work, as the German psychiatrist Hermann Simon had advocated and demonstrated during and after World War I.

Toward the end of the 1930s George Bell, a young Scottish psychiatrist, was so dismayed by the prison-like atmosphere of the first mental hospital in which he worked that he made it his ambition to direct a hospital in which there would be no locked doors. He was appointed superintendent of Dingleton Hospital in Melrose in 1939 and at once started to open its locked wards. In spite of the interruption of six war years, he persevered, educating his nursing staff and the surrounding community into a new tolerance for harmless eccentricity on the part of his patients. By 1949, the last ward was unlocked; by this time the Melrose rugby team had come to appreciate the presence of a strong body of supporters from Dingleton Hospital whenever they played on their home ground.

Two other contemporaries of George Bell, Duncan MacMillan of Nottingham and T.P. Rees of Croydon, soon followed suit in opening all their wards, but for them this was only one aspect of very comprehensive rehabilitation programs aimed at remedying and, if possible, preventing the apathy associated with prolonged hospital stay. Together with Arthur Bowen of York, they were also pioneers in linking the work of the psychiatric service closely with that of the social services, which would become responsible for the patients' aftercare. By their own exertions, each of these succeeded in creating a network of community care that has not yet been matched in the country as a whole.

Two other outstanding figures in modern British psychiatry deserve special mention, Maxwell Jones and R.D. Laing. I find their contributions fascinating because they exemplify the contrasting accomplishments of two charismatic figures, one of whom always kept one foot on the ground while the other took off into the clouds. Maxwell Jones's special contribution was to teach us, by his example, how to create a genuinely therapeutic community in which the contributions of nurses, occupational therapists, social workers, relatively untrained "social therapists," and, above all, the patients themselves were all employed in the task of understanding and helping those who were experiencing mental or emotional problems. Here I speak as one who has tried to copy Maxwell Jones's techniques in my own clinical work: imitation is the sincerest form of flattery.

R.D. Laing will be remembered for his remarkable intuitive insight into the experience of the schizophrenic individual and for the generosity and compassion that have inspired his form of treatment. However, he will be remembered less flatteringly for his flights of speculation (less in evidence now than in the late 1960s) that seemed to claim that a schizophrenic breakdown can be a rewarding experience, a "journey to the interior of the self" from which one can return with one's personality enhanced. This sounds wonderful, especially in Laing's eloquent prose, but there are all too few returned travelers who can vouch for the authenticity of his claims.

A sketch of British psychiatry over the past two centuries would not be complete without referring to the striking improvement in the quantity and quality of research and training in the field during the past 30 years. This was due in very large measure to the work of Sir Aubrey Lewis and his collaborators at the Maudsley Hospital, London. For more than a generation practically every leading psychiatrist in Britain had part or all of his/her scientific training at the Maudsley. Today Sir Aubrey's former students chair most of the country's university departments of psychiatry. The other main source of research and new ideas has been the Tavistock Clinic and its associated Institute of Human Relations. Its role as a center of psychoanalytic training and for applying psychoanalysis in industry and in life in general was the more important because of Lewis' hostility to psychoanalysis.

Some critics have argued that Sir Aubrey's influence was largely negative. By stressing the importance of the scientific method and, above all, of the critical evaluation of etiological theories and therapeutic claims, he and his followers succeeded in clearing away a great deal of dead wood. Today we are much more modest in our claims of understanding the processes underlying mental illness, but at least our modicum of knowledge has a firm scientific base; this was not so before Sir Aubrey's contribution.

In this paper I have paid particular attention to fluctuations in the humane or libertarian care of the mentally ill. I have indicated that fluctuations and, indeed, regressions in the standard of care have been most evident when the advocates of particular reforms became overenthusiastic, made excessive therapeutic claims, and raised hopes that in the long run were doomed to disappointment. There is an interesting paradox here. The very enthusiasm and confidence of those who conduct any therapeutic regimen have repeatedly been shown to contribute to its success, but this apparently continues to hold true only as long as the confidence is reality-based. In other words, enthusiasm alone is not enough; it has to be underpinned by procedures that of themselves (not merely because of the personality of the therapist) are capable of effecting change.

This calls for a combination of two rather different qualities of temperament. Zealous reformers tend to be emotionally committed, in a hurry to do good, and impatient of criticism as to whether their innovations are going to be helpful to patients in the long run. They want action without delay and are convinced that any action that is generous in intention must be beneficial. Unfortunately, this has often proved to be a false assumption.

On the other hand, those with a bent for verification are less concerned with action for its own sake than with action that has been proved to be efficacious. There is a genuine conflict between these two temperaments that can find expression in mutual hostile criticism. It can also find more constructive expression

when the enthusiasts recognize the need to verify and, perhaps, in the light of operational research, to modify their expectations and when the evaluators give due credit to reformers for the initial impetus without which improvements in care could never be achieved.

Only when the enthusiasts and the evaluators work together will we see a lessening in the fluctuations of emphasis in patient care. Reforms of proven worth will then become accepted as standard practice instead of relying on some individual's personal leadership and drive. The surest defense against false hopes and relapses into inhumanity and neglect lies in our willingness to tolerate criticism and to apply it where we see the need for it.

TWO CHALLENGES TO PSYCHIATRY

Two major challenges confront the discipline of psychiatry at the present time: 1) the unconstructive hostility of various schools of antipsychiatry, whose denial of the reality of mental illness and of the physician's role in helping the mentally ill has raised great hopes among the general public, and 2) the political abuse of psychiatric diagnosis and treatment, particularly in the USSR.

Antipsychiatry

In antipsychiatry we see an example of a generous, liberating movement that has turned sour because it was partially based on unreal expectations. When this happens the "liberators" very often seek a scapegoat, some group of individuals who they believe are actively thwarting the achievement of their humane goals.

Antipsychiatry offers us an opportunity to put into practice that readiness to listen to criticism to which I referred above as the best defense against lapsing into dogmatism and error. When I say listen to criticism, however, I do not necessarily mean to accept it; rather, we should examine the critic's arguments as dispassionately as we can and remain open to change when we find them well founded. I believe there are many genuinely compassionate, generous, and well-motivated people among the antipsychiatrists. They are playing an important role in compelling us to reexamine many of our assumptions and practices, and the history of psychiatry shows us how important it is that such reexaminations be carried out—whether by psychiatrists such as Philippe Pinel or R.D. Laing or by concerned laypeople such as the Tukes (the founders of the Retreat at York) or Dorothea Lynde Dix.

The Political Abuse of Psychiatry

The abuse of psychiatry for political ends is, unhappily, only one element in a worldwide regression toward authoritarian, tyrannical regimes that increasingly impose the suppression of criticism, torture, and arbitrary imprisonment without trial in order to buttress their rule. We see particularly gross examples of such regimes today in Chile and in South Korea, but the denial of basic human rights is flagrant in many other countries.

It is principally in the USSR that political dissent has come to be equated with insanity and dissenters forcibly subjected to psychiatric treatment. In a way, this represents the survival of an old Russian tradition. More than a century ago Tsar Alexander I had a military cadet named Zhuko declared insane because he wrote verses about freedom. His successor Tsar Nicholas I decreed the philosopher Chaadaev (a friend of Pushkin) to be insane because he published an article criticizing certain tyrannical actions of the tsar's regime.

In recent years the Soviet regime has been emulating the tsars. Men such as General Grigorenko, Ivan Yakimov, Leonid Plyushch, and Victor Faiberg, who have dared to criticize such Soviet actions as the invasions of Hungary and Czechoslovakia, have not been tried in public but have been secretly declared insane and incarcerated in prison mental hospitals. When the young psychiatrist Semyon Gluzman tried to draw attention to the lack of medical evidence to substantiate the psychiatric diagnosis in several of these instances he was savagely persecuted and is still in prison. Another young man, Vladimir Bukovsky (now 35 years old) was responsible for delivering to the West a 150-page documentation of cases of the wrongful detention in psychiatric hospitals of political dissenters; he has suffered grievously for this highly principled action.

In 1971 Roy and Zhores Medvedev published *A Question of Madness* (4), a most spirited account of their joint struggle to effect the release of Zhores, who was carried off to a mental hospital on insufficient grounds. This book is at once a horror story in its depiction of a Kafkalike regime, and a heartening story, in its revelation of the courage, forthrightness, and sincerity of men like Sakharov, Solzhenitsin, and many others who were—and still are—prepared to speak up in condemnation of such violations of human rights. This struggle is still going on; we owe it to our colleagues in the USSR to support them in their fight against the perversion of psychiatry.

The World Federation for Mental Health was among the first to protest such actions; it has done so at each of its biennial world congresses since 1971. The agenda of the VI World Congress of the World Psychiatric Association includes a discussion of the Declaration of Hawaii, which is a code of psychiatric ethics with such statements as "The psychiatrist must never use the possibilities of the profession for maltreatment of individuals or groups" and "The psychiatrist must not participate in compulsory psychiatric treatment in the absence of psychiatric illness."

To support such declarations is not to be anti-Russian. On the contrary, it is to align ourselves with a courageous, patriotic group of Soviet citizens who have reproached their own country for having misused psychiatry to deprive citizens of basic human rights. The dissidents appeal to the same high ideals and re-

spect for human freedom and human dignity that inspired their own twentieth-century revolution and that in earlier centuries inspired England's Magna Carta, the French Revolution, and the Declaration of Independence of the United States. Freedom of the human spirit has had to be defended many times in the past. Today those Russians who, at great personal risk, protest the abuse of psychiatry to suppress dangerous thoughts are in the forefront of this struggle. They deserve our support.

Referrals Sought for NIMH Program

The Intramural Program of the National Institute of Mental Health is seeking referrals of patients with anxiety states, depression, mania, amphetamine and cocaine addiction, acute and chronic schizophrenia, and tardive dyskinesia; also, anorexia nervosa, Huntington's chorea, presenile dementias (e.g., Alzheimer's and Pick's), Korsakoff's syndrome, Gilles de la Tourette's syndrome, hyperactivity, and enuresis in children.

Patients with these diagnoses are sought to participate in clinical-research studies designed to elucidate the role of biochemical, genetic, familial, and socioenvironmental factors in psychiatric illness and to assess treatment modalities. A goal is the significant integration of knowledge regarding central nervous system functioning in animals with that of human beings, with the hope of increasing its applicability to humans for improved diagnosis and treatment of psychiatric and neurologic disorders.

A physician referral is a prerequisite for admission, and a written medical summary is helpful. Referrals are made through Stanley I. Hirsch, L.C.S.W., Room 3N-250, at NIMH Clinical Center, 9000 Rockville Pike, Bethesda, Md. 20014; telephone (301) 496-5111. Mr. Hirsch will arrange with the appropriate unit to schedule a screening date.

Teaching Psychological Medicine to Family Practice Residents

BY ERWIN R. SMARR, M.D., AND ROBERT BERKOW, M.D.

The authors describe the development of a curriculum focused on teaching residents in family practice how to recognize and deal with the psychological issues presented by patients and by their own reactions to patients. They describe how teachers in a medical school's divisions of family practice and psychosomatic and liaison psychiatry collaborated to develop an integrated training program and the changes this program effected in the attitudes and understanding of residents. They found that residents in this program shifted their emphasis from a narrow view of traditional medical diagnosis and treatment to a broader psychological-biological understanding of patients.

THE RENEWED EMPHASIS on family practice and the development of new training programs in primary care stress a humanistic approach and comprehensive patient care, both of which recognize the need for skills in psychological medicine. The standards for accreditation of family practice residencies require substantial psychiatric training, but neither those standards nor any current body of pedagogic knowledge provides a generally accepted core curriculum. This paper will describe our approach to curriculum development at Hahnemann Medical College and Hospital, our teaching processes, and the changes we have observed in our residents.

In July 1974 the Division of Family Medicine of Hahnemann Medical College approached the Division of Psychosomatic and Liaison Psychiatry with the idea of collaborating to develop an integrated training program. The traditional rotation through psychiatric inpatient services, psychiatric case consultations, and formal lectures had many defects. A new approach, based more on actual family practice, was needed.

Family practitioners need to learn about psychosis, neurosis, and behavior disorders. However, they usually see patients with overt psychopathology at different stages and in different forms and contexts than the psychiatrist or the psychiatric service sees them. Family practitioners often deal with the psychological problems of everyday life, which are often interwoven with a variety of illnesses, rather than with overt psychiatric symptoms.

Psychiatric consultants, on the other hand, respond only to preselected cases of the referring physician. Thus they become the problem solvers rather than the teachers of physicians in the processes of diagnosis, evaluation, and management in physician-patient situations. Psychiatric advice is usually directed to only the most immediate problems and tends to be tailored to basic levels that can be understood and applied with certainty, considering the limitations of the referring physician.

PROGRAM DESCRIPTION

Personnel and Schedules

Although the family medicine division knew what it did not want for its 9 residents, it was much more difficult to define what was needed. Out of the dialogue between the two divisions of family medicine and psychosomatic and liaison psychiatry came a commitment to create a new clinically oriented program of psychosomatic medicine. The program's basic design was that of a preceptorship centered on family medicine patient-physician interactions.

A liaison psychiatrist made inpatient family medicine rounds 2 hours a week with the medical chief and a medical sociologist who was a full-time staff member in family medicine. The outpatient precepting and conferences were conducted by two part-time staff members of the liaison psychiatry division, one of whom (E.R.S.) is a psychiatrist with special interest and experience in general medical practice and the other (R.B.) an internist with subspecialty training in psychosomatic medicine. Each contributed half of the teaching time required. Nine residents were involved in this program in its first year; the number has increased to 17 in the third year, with no change in the number of teachers.

In the outpatient Model Family Practice Unit, all residents were precepted individually during their patient interviews and participated in one of two separate group conferences (each lasting at least 1½ hours) a week; the family medicine faculty and the medical sociologist participated. A total of 12 hours of teaching a week, supplemented by monthly didactic lectures for the full 3 years, was planned. The family medicine di-

vision, whose faculty consisted of two full-time and two half-time staff members, funded the salaries.

Curriculum and Program Design

Decisions on curriculum content were deliberately not made because of our conviction that as long as the work focused on the problems of residents and patients the appropriate curriculum would emerge. Additional presuppositions that contributed to our basic approach included the following: that it was mandatory to examine the psychological elements observed in each and every patient contact without prejudging whether or not these elements were important; that effective modeling by psychologically sophisticated faculty is a sine qua non of learning by identification; that unlearning of role models developed during medical school would be necessary; and that teaching would be associated with unconscious resistances and biases. The latter problem was to be dealt with through teaching rather than by psychotherapy.

Teaching focused on three broad areas: 1) psychological-biological interactions, i.e., when and how people become diseased and modifications in the course of disease; 2) psychic stress, processes, and pathology in different modes of illness, i.e., somatic, cognitive, emotional, and behavioral; and 3) physician and patient roles, i.e., their separate individual defenses, their interactions, and sociocultural aspects of illness and medical care systems explicitly analyzed, defined, and then modified according to particularized aims rather than stereotyped.

The general philosophical and pedagogic background for this approach to teaching an integrated psychosomatic perspective lies in the earlier work and writing of others (1–5). Our efforts were directed to developing practical applications in nonpsychiatric residency training. The program as a whole was continuously monitored through regular 2–3-hour faculty conferences held every 6–8 weeks as well as through interim informal discussions, which allowed modifications and provided concurrent evaluations of residents, teachers, and the program. Later, an evaluation form became the basis of more objective measurement of each resident and periodic review of the goals and progress of each resident. We estimated that it would take about 3 years for the faculty to delineate and transmit the relevant curriculum and requisite skills and for the residents to genuinely incorporate them into routine practice. After 3 years the residents should be capable of continued growth on their own. However, the total effect could not be known until the postresidency years of practice.

We wish to emphasize that preplanning a curriculum would be contrary to the goals of the program. After the first year and a half a curriculum emerged and substantial changes in attitudes and practices of the residents were apparent. This paper will describe the content that emerged and the important processes observed during outpatient precepting and conferences.

PROGRAM RESULTS

Curriculum Development

In evaluating curriculum development, the initial tabulation of discussion subjects presented by our residents from their experiences with patients yielded almost 100 subjects within less than a year (see appendix 1). The list represents a typical range of psychologically significant outpatient problems seen by family practitioners. Although the two conferences held each week were led by two teachers with different backgrounds, there was about 80% correspondence in content between them in the first year. Content differences between the two conferences were related to the composition of the resident groups, presentations of patients, and differences in background of the teachers. The items enumerated in appendix 1 can be broadly grouped in many ways, and it should be recognized that each subject was usually discussed from several perspectives. For example, in discussing obesity, the etiological psychodynamics of this disorder are important, but evaluation and management must also take cognizance of social factors and the physician's attitudes, reactions, bias, and interviewing techniques.

Among the medical problems per se, the following appeared most often: hypertension, headache, obesity, ulcer, alcoholism, insomnia, death and dying, problems of pregnancy, cancer, and impotence. Because Hahnemann is an urban teaching center, the social problems of poverty, ghetto life, racial and subcultural influences, religious effects, unemployment, and divorce naturally arose.

Although many clinical syndromes and psychopathological processes were discussed in the conferences, an equally large number of subjects dealt with the physician's role, attitudes, and resources. These subjects could possibly have been preplanned and approached in a didactic program, but the advantages of having the topics raised by the residents themselves and providing timely critical discussion in direct response to immediate clinical needs were especially valuable.

Most subjects could not have been taught as effectively didactically or from a curriculum isolated from the residents' experience. Active versus passive, authoritarian versus laissez-faire, medical model versus psychiatric model styles of doctoring; the moral and ethical issues that underlie so many fine points in case management; and unconscious decision making continually emerged as topics for discussion and were dissected in conferences. All aspects of interviewing technique were examined, changing the concept of the interview from a purely medical history taking to a conscious psychodynamic analysis from which appropriate psychotherapeutic management could proceed. The physician's own feelings and reaction patterns could be perceived as influences affecting his/her style and impact in different situations.

Ordinary family practice yielded a full range of clinical psychopathology and ample opportunity to teach

differential diagnosis and management. Developmental psychology, although also taught separately in child psychiatry, came under review in case discussions. Learning techniques of supportive psychotherapy as well as principles affecting referral for more specialized treatment helped residents define their own appropriate psychiatric skill levels and limits.

Teaching Processes

In precepting, several processes were conceptually and operationally important. For example, interviewing techniques were looked at closely (by direct observation and with the aid of tape-recordings), and medical histories were reexamined with a psychiatric focus, sensitizing residents to emotional nuances and hinted-at conflicts that are routinely excluded from attention by the standard medical interview. Our residents were impressed when they discovered what they had been missing. However, unless they were taught how to collect the relevant data themselves, this new awareness led only to frustration. This often required that they become aware of their own prejudices and defensive mechanisms that predetermined not only what they perceived but how they acted.

As the residents learned to gather psychosocially significant data, the preceptors were challenged to help them organize and synthesize them with psychosomatic concepts. This involved the two prevalent types of logic in medical practice: diagnostic reasoning and management (or therapy) planning. We also found it important to implement reasonable conclusions and follow the subsequent events.

A pertinent and important question is just how much is appropriate for nonpsychiatric physicians to learn regarding such specialized aspects of psychology as defenses, transferences, and psychodynamics. These processes came up for discussion quite naturally in the course of teaching how to interview and understand patients and their problems in broader perspective.

As in every group process, resistances to change or to program features were manifest either actively or passively. The group conference format provided the means of bringing these issues into direct discussion.

Resident Responses

Through the group process our residents have become more analytical with themselves and each other. Emphasis has shifted from the narrow traditional medical diagnoses and usual treatments to a much broader psychosocial, biological inquiry in which patients and their problems are viewed as uniquely human organisms responding to stresses with a variety of mechanisms (defenses) to maintain or achieve homeostasis (2).

A formal evaluation form has been designed and will be described in a subsequent paper. Preliminary data indicate that without teaching our residents psychiatry per se they have learned the following: 1) an appreciation that looking at psychosocial data saves time and is effective in dealing with medical problems; 2) how to use spontaneous verbalizations rather than cut them off; 3) to be aware of transferences and countertransferences that affect what patients say and do, the course of the physician-patient relationship, and the outcome of treatment; 4) how to recognize patient defenses and deal with them; 5) to be aware of their own emotional reactions (not due to countertransference) affecting the interview; 6) the psychodynamics of object-relationship conflicts behind such phenomena as somatizations, depressions, and neurotic symptoms; 7) to avoid being caught up in neuroses, manipulations, or acting-out of problems; and 8) to incorporate psychodynamic logic in the diagnosis and management of medical disorders.

The residents have come to use diagnostic procedures and treatment methods differently. They have learned that ordering laboratory tests is part of the communicative process and mutual search and how to use these elements in the diagnostic process to enhance basic trust and confidence in the physician. Instead of seeing tests and prescriptions as purely medical or scientific processes, the residents have come to understand these in the context of the transference. They have also recognized that the quality of the physician-patient relationship affects the treatment result. After first dealing with their own anxiety and defenses, residents have been relieved by being able to interact more naturally. Patient confidence has been established on the basis of genuine respect rather than authoritative awe or seduction. Equally important, the resident has learned to do what is important and necessary to cope with emotional aspects of patients' problems rather than avoiding them out of fear or ignorance.

Program Modifications

The program has changed only slightly since its inception. We have become even more convinced that precepting family practice residents in their usual patient care settings, using the group process methods, and providing new role models for identification are effective methods of teaching. A curriculum suitable to the program needs has evolved spontaneously. The precepting process supplanted formal lectures. In the second year of the program didactic lectures were dropped except as they were requested by the residents. A more structured presentation of the emerging core curriculum may be added at a later date.

Twin Relationships and Depression

BY MARIA PALUSZNY, M.D., MELVIN L. SELZER, M.D., AMIRAM VINOKUR, PH.D., AND LARRY LEWANDOWSKI, M.A.

The authors investigated closeness and other variables measuring depression in 22 identical and 13 fraternal twin pairs. Each twin rated him/herself on a two-part questionnaire; part 1 included questions on demographic characteristics and the twin relationship, and part 2, the Zung Self-Rating Depression Scale, measured depressive symptoms. There was a high degree of agreement across all variables for the total sample, and degrees of depression were comparable to that in the general population. Closeness was found to be inversely correlated with depression. The authors suggest that future studies include other groups (siblings, spouses, etc.) and follow-up data.

TWIN STUDIES frequently focus on the negative aspects of the intertwin bond. Problems with development of self-identity (1), prolonged mutual dependency (2), and intertwin rivalry (3) have been described. In addition, the twin relationship can enhance a preexisting psychiatric disturbance, as has been noted in psychotic twins (4) and in selective mutism (5). Conversely, it appears that the intertwin relationship can serve as a special support during stress (6). Keeping these factors in mind, we were interested in comparing the relationships of a sample of identical and fraternal twins and correlating the data with depressive symptoms in the twin population. We wondered if our data would enable us to ascertain the importance of closeness (and other variables) in the twin relationship. The questions we were interested in include the following:

Does closeness in the twin relationship promote dependency and loss of self-identity and enhance depressive symptoms? Or does the twin serve as an important support object, diminishing the likelihood of depression?

To assess the twin relationships, we compared and contrasted self-rated variables that measured the intrapair relationships and similarities in a twin population; we then compared these variables with depressive symptoms.

Adequate exploration of intertwin relationships and depression would necessitate individual psychiatric interviews to quantify depression (7) and to delineate precisely the intertwin bond, and extensive data gathering would be necessary to obtain a control sample. Because we were unable to do such an involved study at this time, we decided to use self-assessment methods to obtain preliminary data.

The Zung Self-Rating Depression Scale (SDS) is a simple 20-item questionnaire that measures depressive symptoms (8, 9). It has been used frequently in depression research and according to Blumenthal (10) "appears to have the validity, reliability, and replicability so important in epidemiological research." Although the scale's uses are limited and it has been criticized as a diagnostic tool, especially in controlled drug studies (7), the SDS appeared completely adequate for the purpose of our study.

METHOD

Subjects

Our sample consisted of 70 twins (35 pairs); 22 pairs were identical and 13 were fraternal. In previous studies it has been established that twins' perception of zygosity is highly accurate (11). Thus, we accepted the twins' rating of whether they were fraternal or identical without verification by blood typing. All the twins were adults, 18 years or older, and 70% were in the 18–44 age group; 50 were women and 20 were men. Many of the twins were located through twin organizations and others through personal contacts. The questionnaires were either completed in social settings or mailed to the twins. Hence, no strict criteria were adhered to in administering the questionnaire except that the subjects were asked not to compare ratings with their twin.

Questionnaire

The questionnaire consisted of two parts. Part 1 included questions on such demographic characteristics as age, sex, type of twinship, education level, and marital status. These data were used to ensure that our

Dr. Vinokur is Assistant Research Scientist, Institute for Social Research, University of Michigan.

This research was supported by the National Institutes of Health Maternal and Child Health Services Project 923.

sample was representative of the general population on these variables. Each twin also independently rated his/her relationship to his/her twin according to closeness (rated on a 5-point scale from "like part of me" to "distant") and frequency of contact with the twin (rated on a 5-point scale from "few times per week" to "less than once per year").

Similarities to twin were rated on an 11-point scale for appearance, likes and dislikes, hobbies, and feelings about having a twin.

In part 2 the twins rated themselves and their perception of how their twin would rate him/herself on the SDS.

From these data we assessed whether 1) a close relationship to another person (in this case the twin) correlated with lower levels of depression as measured by the SDS, 2) depression in both twins was equally evident, and 3) twins were able to see their twin's symptoms accurately or would tend to project, i.e., see their twin as being as depressed (or nondepressed) as themselves. We also wondered if there was a significant difference between identical and fraternal twins.

RESULTS[1]

Twin Comparisons

Intrapair analysis revealed a strong level of agreement within twin pairs regardless of whether they were identical or fraternal. The one exception was that fraternal twins rated themselves as significantly different in likes and dislikes than their twin partner ($p<.05$).

Despite the within-pair agreement, further comparisons were made to explore possible differences between identical and fraternal twin pairs. Because both the identical and fraternal twin groups are composed of paired observations, it was necessary to take the average rating of each twin pair before making any between-group comparisons. This statistical manipulation offered a less biased measure by creating one observation for every twin pair. Comparisons were then made between 22 observations for identical twins and 13 observations for fraternal twins across six variables.

Significant differences were found between identical and fraternal groups on all but one variable, frequency of contact. On five other variables the identical twin versus the fraternal twin ratings showed that 1) identical twins feel closer to each other ($p<.01$); 2) identical twins like having a twin more than fraternals do ($p<.05$); identical twins are more alike in appearance ($p<.01$); identical twins have more similar interests ($p<.01$); and identical twins tend to like and dislike similar things more than fraternal twins do ($p<.01$).

Furthermore, with the identical twins, a strong correlation was found between closeness and liking having a twin ($r=.8016$, $p<.001$). Thus, it appeared the more the identical twins liked being a twin, the closer they felt to each other. The fraternal twins did not show a significant correlation between closeness and liking being a twin. However, a significant correlation was found between how often the fraternal twins saw each other and similarity of interests ($r=.9590$, $p<.01$). One could speculate that frequency of contact was prompted by sharing activities that both fraternal twins enjoyed rather than being prompted by other variables.

We found no significant difference in a comparison of single versus married twins in terms of feelings of closeness to their twin. Although single twins tended to see their twin slightly more often than married twins, this difference was not significant.

Depressive Symptoms

Interesting data emerged when we correlated the 6 variables with the SDS. The mean SDS score for the total sample was 31.5, very close to the SDS score of 33 that Zung found in his normal control groups (8). In this regard the twins appear similar to a normal population and comparable to the "normal" range as described by Blumenthal (12). No correlation in the twins' perception of their relationship was found between the SDS and similarity in appearance, similarities in likes or dislikes, or frequency of contact. Weak but statistically nonsignificant correlations were found between SDS and similarities of interests (hobbies) and how the twins felt about having a twin. The only significant correlation was between the SDS and the ratings of how close the twins felt to each other ($r=.26$, $p=.03$). Thus, it appears the closer the twins felt to each other, the less likely they were to show depressive symptoms as measured by the SDS.

Evaluation of the similarity of SDS scores between twin pairs revealed an SDS correlation of .70 ($p<.01$). When we divided our sample into fraternal and identical groups, we found that the correlation was much higher for the identical group ($r=.80$, $p<.001$).

We assessed how much the twins tended to project their own depressive symptoms onto their twin by comparing difference scores between twin ratings with a rating for accuracy. This method has been described previously (13). Basically, a difference score was obtained between the twin's own SDS and the SDS the twin filled out for his/her twin. This score was then compared with the difference of the SDS score of the twin and the person's own SDS score. In calculating projection in this manner, we found that the twins saw their twin as equally depressed (or nondepressed) as themselves. However, even though the total sample showed this tendency, we found a major difference when we looked at identical and fraternal twins separately. Identical twins significantly projected their own perceptions of depression ($p=.02$), but projection of depression by the fraternal twins was not significant.

[1] Statistical tables are available from Dr. Paluszny on request.

DISCUSSION

Our sample of 70 twins appeared to be very similar in how they rated themselves and their twins. There was a high degree of agreement across all variables for the total sample. The identical twins, however, liked being a twin more, felt closer to their twin, and rated themselves as more similar to their twin in appearance, interests, likes, and dislikes than the fraternal group. In assessing the negative and positive effects of this closeness, we found closeness to one's twin did not correlate with frequency of contact or with staying single. Thus, closeness did not seem to interfere with the twins separating from each other.

The total sample showed degrees of depression comparable to that found in the general population. The twin pairs, especially the identical twins, showed a similarity in their depressive scores. Likewise, the identical group, more than the fraternal group, tended to "project" their own ratings on the SDS, viewing their twin as similarly depressed (or nondepressed) as themselves.

The degree of depression showed an inverse correlation with closeness, i.e., the closer the twins rated themselves, the less likely they were to show depression. A word of caution is necessary pertaining to this finding. The correlation between feeling close to one's twin and low level of depression might suggest a causal relationship between the two phenomena, i.e., closeness of feeling decreases depression. Such a conclusion, however, is unwarranted at the present time. It is quite possible that the experience of depression in itself leads a person to feel quite distant from those significant others who surround him. This finding, however, does seem to indicate that closeness in twins does not lead to psychiatric problems that become clinically evident as depression.

Future studies to investigate closeness and other pertinent questions regarding depression (including the role of hereditary factors) should include such additional groups as siblings, spouses, and friends and should involve longitudinal (follow-up) data collection.

Editor's Note: We are aware that there will be criticism about the publication of these papers. The editors are especially concerned about their unevenness. However, in view of the widespread interest in and strong differences of opinion about the subject, we decided to give it a full airing. F.J.B.

Myths of "Shock Therapy"

BY MAX FINK, M.D.

The author discusses the myths of the ECT process—that shock and the convulsion are essential, memory loss and brain damage are inescapable, and little is known of the process—and assesses the fallacies in these ideas. Present views of the ECT process suggest that its mode of action in depression may best be described as a prolonged form of diencephalic stimulation, particularly useful to affect the hypothalamic dysfunctions that characterize depressive illness. The author emphasizes the need for further study of this treatment modality and for self-regulation by the profession.

"SHOCK THERAPY" is a treatment that has been in clinical use since 1937. It is one of many treatments that evolved after the success of fever therapy in relieving CNS syphilis led to a hope that mental illness was not necessarily incurable.[1] Of many similar heroic measures that were tested amid this enthusiasm—insulin shock, camphor, pentylene tetrazol (Metrazole), cardiozole, sleep therapy, lobotomy, and ECT—only ECT continues to be used frequently. Despite improvements in its application, the use and study of ECT are hampered by some widely held beliefs that are often contradictory and confused.

In a lead article in the *British Medical Journal* in 1975 it was stated that "Shock and convulsion, even if the latter is modified almost to the point of invisibility, are of the essence" (1). Also in 1975, a psychiatrist writing in *Psychiatric News* said,

> ECT has been abused. It has been given too often, too broadly, and for whom the treatment was not indicated. . . . The skill that it takes to administer the actual shock to a patient is negligible. It is about as involved as the skill required to take a patient's temperature. True, there are variations in the placement of electrodes on the patient, and there are different ways of administering the current, but none of these techniques require the background of a psychiatrist's intensive training or would take more than a few minutes for *anyone* to master. (2)

An internationally known psychologist, in an interview in the newsletter of the American Psychological Association, said, "I'd rather have a small lobotomy than a series of electroconvulsive shock. . . . I just know what the brain looks like after a series of shocks, and it's not very pleasant to look at" (3). A resident neurologist, attacking the clinical use of ECT in a lay journal, stated that "Electroconvulsive therapy (ECT) . . . is remarkably widespread, demonstrably ineffective, and clearly dangerous. It causes brain damage manifested in such forms as severe and often permanent loss of memory, learning disability, and spatial and temporal disorientation" (4).

Critics assert that "shock" and the convulsion are

Revised version of a paper presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.
